## Abstract

We characterize efficiency in an equilibrium model of investment and capital reallocation with heterogeneous firms facing collateral constraints. The model features two types of pecuniary externalities: collateral externalities, because the resale price of capital affects collateral constraints, and distributive externalities, because buyers of old capital are more financially constrained than sellers, consistent with empirical evidence. We prove that the stationary-equilibrium price of old capital is inefficiently high, because the distributive pecuniary externality exceeds the collateral externality, by a factor of two in our calibrated model. New investment reduces the future price of old capital, providing a rationale for new-investment subsidies.

# 1 Introduction

Financial frictions, such as collateral constraints, distort the level of aggregate investment and the allocation of capital across firms. What is the allocation of capital that maximizes welfare given financial frictions? To address this question, we develop an equilibrium model of investment and capital reallocation with collateral constraints. We then characterize the constrained-efficient allocation, that is, the allocation that would arise if a benevolent planner made investment decisions on behalf of firms, using the same markets and subject to the same frictions firms face in the competitive equilibrium. By characterizing this benchmark and comparing it with the decentralized equilibrium, we find that the constrained-efficient allocation features a higher level of investment, a larger volume of capital reallocation, and, crucially, a lower resale price of capital.

In our framework, heterogeneous firms face collateral constraints on borrowing as well as costs of issuing equity. Over time, they accumulate net worth and respond to productivity shocks by investing in new capital, or by acquiring old capital from other firms. Old capital is reallocated in a competitive secondary market. Importantly, the model is consistent with the key facts about capital reallocation: On average, older assets flow to more financially constrained and more productive firms. These firms have a high marginal value of current net worth. Thus, they take advantage of the fact that old capital is cheaper and has hence a lower financing need than new capital, because it has a lower future residual value. On the other hand, larger, less financially constrained firms tend to acquire newer investment goods, as they effectively discount the future resale value of capital at a lower rate. These firms account for most of the formation of new capital in the economy, and typically resell their capital on the secondary market as it ages.

Because of financial frictions, the competitive-equilibrium price of old capital does not coincide with its social value: Financial frictions manifest themselves as pecuniary externalities. Specifically, our economy encompasses both collateral externalities, because the resale value of capital affects firms' ability to borrow, and distributive externalities, because buyers and sellers of old capital have different valuations of internal funds. We show that the price of old capital, which serves as collateral, affects the aggregate value of these externalities with opposite sign. On the one hand, a *higher* resale price of capital relaxes collateral constraints. On the other hand, because buyers of old capital tend to be more financially constrained than sellers, a *lower* price of old capital redistributes resources toward firms with a higher marginal product of capital.

Our main result is that this distributive externality is larger than the collateral externality in stationary equilibrium. As a consequence, the equilibrium price of old capital is higher than the constrained-efficient price. An additional unit of new investment today

increases the supply of old capital in the future, thereby reducing its price and creating a positive externality on future constrained firms, who are net buyers of old capital. In the decentralized equilibrium, investing firms do not take this effect into account. A subsidy on new investment may thus lead to a more efficient allocation.

Importantly, a low price of old capital is optimal, despite its negative effect on the value of collateral. The economic intuition is that the buyers of old capital are the most constrained firms, whereas the firms that purchase new capital and borrow against its collateral value are less constrained or unconstrained. Thus, the marginal value of net worth of firms that benefit from the distributive externality of a lower price of old capital is higher than the marginal value of net worth of the firms that are negatively affected by the collateral externality of a lower price of old capital.

To formalize this result, we consider a planner who faces the same constraints and has access to the same markets as private firms, but, crucially, internalizes all pecuniary externalities. The planner needs to respect all individual budget constraints and cannot redistribute net worth across firms, that is, cannot “remove” financial frictions. We solve for the constrained-efficient allocation and compare it with the stationary competitive equilibrium. We show, both analytically and quantitatively, that the price of old capital is inefficiently high in competitive equilibrium. The constrained-efficient allocation induces a lower price of old capital, allowing financially constrained firms to produce at a higher scale and to grow their net worth faster.

Our analysis is organized in two parts. First, we consider a stylized infinite-horizon model of capital reallocation and pecuniary externalities with over-lapping generations of firms and capital that lasts for two periods. In this model, we characterize the stationary equilibrium analytically and obtain a formal result on the sign of the inefficiency in equilibrium: The distributive externality is larger than the collateral externality. Importantly, this result holds independently of specific assumptions about the distribution of net worth. We then provide a closed-form solution for the constrained-efficient allocation, as well as a Ramsey implementation of this allocation with proportional subsidies on purchases of new capital, and taxes on purchases of old capital. We also show that our key analytical results obtain under several relevant generalizations of our assumptions, namely entrepreneurial risk aversion, heterogeneity in productivity, and when both firms and capital goods are long-lived.

Second, we consider a richer quantitative model with persistent idiosyncratic productivity shocks and long-lived firms and capital, which nests our stylized model. We calibrate the model to match empirical moments related to US firm dynamics and financing costs, and use it to perform a quantitative efficiency analysis, with a main focus on the stationary

equilibrium. We find that the distributive externality is over twice as large as the collateral externality in competitive equilibrium. Moreover, output and consumption are respectively 10% and 7% lower than in the first-best allocation. The constrained-efficient allocation recovers approximately 70% of these losses (7 percentage points of output and 5 percentage points of consumption), by substantially decreasing the price of old capital. This outcome can be implemented in competitive equilibrium, with a mix of subsidies on new investment and taxes on purchases of old capital. We also consider the case of a single policy instrument, namely a new-investment subsidy, and find that it should be positive, again to induce a lower price of old capital. However, this restriction on the policy instrument set may have a significant welfare cost, as it only allows the planner to recover a smaller fraction of the welfare losses induced by financial frictions.

The paper proceeds as follows. Section 2 discusses the related literature. Section 3 presents our main theoretical results in a stylized model of capital reallocation. Section 4 introduces the model with idiosyncratic productivity shocks and characterizes the constrained-efficient allocation. Section 5 presents our quantitative results. Section 6 discusses additional analyses, including transition dynamics. Section 7 concludes.

## 2 Related Literature

This paper contributes to several strands of literature, specifically on capital reallocation and the role of secondary markets, on pecuniary externalities with collateral constraints, on constrained efficiency in dynamic heterogeneous-agent economies, and on the effect of financial frictions on capital misallocation.<sup>1</sup>

*Capital reallocation and secondary markets.* Several papers study the reallocation of durable assets across heterogeneous producers, starting with Eisfeldt and Rampini (2006). A robust empirical finding of this literature is that financially constrained agents tend to buy assets in the secondary market. In particular, Eisfeldt and Rampini (2007) analyze investment in new and used capital in the presence of financial frictions, and present empirical evidence that more financially constrained firms tend to acquire older investment goods, using both the Annual Capital Expenditure Survey and micro data on commercial trucks. More recently, Ma, Murfin, and Pratt (2020) leverage a large dataset on equipment transactions to document a negative correlation between firm age and capital age. We relate our quantitative results to their estimates. Gavazza, Lizzeri, and Roketskiy (2014) provide

---

<sup>1</sup>To focus on the effects of collateral constraints on the efficiency of investment and capital reallocation, we abstract from adverse selection (as in the seminal paper of Akerlof, 1970), illiquidity due to search frictions (as in, for example, Gavazza, 2011, 2016, Ottonello, 2018, and Wright, Xiao, and Zhu, 2020), and heterogeneity not due to differences in net worth or productivity (as in, for example, Bond, 1983).

a quantitative analysis of the welfare gains due to secondary markets for durable goods in the presence of consumer heterogeneity. Gavazza and Lanteri ([forthcoming](#)) emphasize the role of secondary markets in reallocating used consumer durable goods from wealthier to poorer households and argue that this mechanism contributes to the transmission of credit shocks. Lanteri ([2018](#)) analyzes the market for used investment goods in a quantitative business-cycle model with heterogeneous firms subject to idiosyncratic productivity shocks. Rampini ([2019](#)) analyzes the effects of asset durability on the financing of investment with collateral constraints.<sup>2</sup> We build on his model and develop a quantitative framework with idiosyncratic productivity shocks and a general depreciation schedule for capital. Different from the existing literature on capital reallocation, our focus is on efficiency.<sup>3</sup>

*Pecuniary externalities and constrained efficiency.* Several papers study pecuniary externalities related to asset prices in economies with collateral constraints—as introduced by Kiyotaki and Moore ([1997](#))—or other financial frictions. In a seminal contribution, Lorenzoni ([2008](#)) develops a finite-horizon model with production heterogeneity between borrowers and lenders and aggregate shocks, and emphasizes how financial frictions may induce an inefficient level of borrowing and investment. Dávila and Korinek ([2018](#)) show that, in general, financial frictions may give rise to both distributive externalities, that is, externalities between sellers and buyers of assets, and collateral externalities, that is, externalities deriving from the dependence of financial constraints on asset prices, and that prices could be too high or too low.<sup>4</sup> In quantitative analyses of models with pecuniary externalities stemming from asset prices, the literature typically focuses on collateral externalities, abstracting from distributive externalities by assuming a representative producer: Bianchi and Mendoza ([2018](#)) and Jeanne and Korinek ([2019](#)) analyze infinite-horizon small open economy models with a representative firm and an asset in fixed supply. In these models, the price of collateral is too low in states of the world in which collateral constraints bind, and optimal policy can improve efficiency by increasing collateral values.<sup>5</sup>

---

<sup>2</sup>Rampini and Viswanathan ([2010, 2013](#)) study a dynamic model of firm financing with tangible assets serving as collateral, deriving the collateral constraints from limited enforcement without exclusion.

<sup>3</sup>Cooper and Schott ([2020](#)) analyze capital reallocation and aggregate fluctuations by formulating a planning problem, but abstract from financial frictions and the related inefficiency. Cui ([2017](#)) studies the effects of financing constraints and partial irreversibility on the cyclicalities of capital liquidation. Ai, Li, and Yang ([2020](#)) study the link between financial intermediation and capital reallocation. See Eisfeldt and Shi ([2018](#)) for a survey of the literature on capital reallocation.

<sup>4</sup>See Diamond ([1967](#)), Stiglitz ([1982](#)), and Geanakoplos and Polemarchakis ([1986](#)) for early contributions on efficiency in the presence of market incompleteness. He and Kondor ([2016](#)) study the role of pecuniary externalities in liquidity management for the efficiency of investment over the cycle. Kurlat ([2020](#)) considers the role of asymmetric information about capital quality for pecuniary externalities and the efficiency of investment.

<sup>5</sup>Michelacci and Pozzi ([2017](#)) characterize the efficient price of land in a small-open-economy model with collateral constraints and measure the collateral externality using data on land prices and economic activity in Italy. Villalvazo ([2020](#)) explores the role of household heterogeneity for sudden stops in a small

We contribute to this literature by analyzing an infinite-horizon model of investment with heterogeneous firms, consistent with the key facts about capital reallocation. We build on the analysis of externalities of Dávila and Korinek (2018) and show that, in the stationary equilibrium of our economy, the distributive externality is larger than the collateral externality. The price of collateral is too high from the perspective of a planner, because the most financially constrained firms are net buyers of old capital, that is, collateral. A related literature analyzes constrained efficiency in dynamic general-equilibrium models with incomplete markets, with a focus on distributive externalities through wages and interest rates: Dávila, Hong, Krusell, and Ríos-Rull (2012) analyze constrained efficiency in the Aiyagari (1994) model; Park (2018) extends their framework to characterize the efficient allocation of human capital; Itskhoki and Moll (2019) analyze optimal development policies that redistribute between workers and entrepreneurs in an economy with financial constraints.<sup>6</sup> Relative to this literature, we apply the same notion of constrained efficiency, but the focus of our paper is on efficiency in investment and capital reallocation. To our knowledge, we provide the first analysis of optimal investment subsidies in the presence of financial frictions.<sup>7</sup>

*Financial frictions and capital misallocation.* A large literature studies the role of financial frictions for the allocation of capital across heterogeneous firms. See, for instance, Buera, Kaboski, and Shin (2011), Midrigan and Xu (2014), and Moll (2014).<sup>8</sup> These papers provide theoretical and quantitative insights on the efficiency gains that could be achieved by *removing* financial frictions. We focus on what gains could be achieved if a benevolent planner were to face the same set of financial constraints as private agents.<sup>9</sup> In so doing,

---

open economy with collateral constraints. A related literature in international macroeconomics analyzes endowment economies in which the relative price of non-tradable goods affects the value of collateral, which is assumed to be income, instead of the value of capital. See, for instance, Bianchi (2011), Benigno, Chen, Otrok, Rebucci, and Young (2013), and Ottonello, Perez, and Varraso (2019). Bianchi and Mendoza (2020) survey both strands of this literature, with capital or income as collateral, and connect them in a model with endogenous investment, in which the price of capital is tied to the price of non-tradable goods.

<sup>6</sup>Nuño and Moll (2018) develop tools to study constrained efficiency in economies with heterogeneous agents in continuous time.

<sup>7</sup>While we focus on a Ramsey implementation of the constrained-efficient allocation, Kilenthong and Townsend (forthcoming) propose a market-based approach to implementing efficient allocations in the presence of pecuniary externalities. Related to our analysis of investment taxes and subsidies, Dávila and Hébert (2020) study the optimal design of corporate taxation in the presence of financial frictions. Parodi (2020) provides a quantitative analysis of optimal subsidies on consumer durable goods in presence of partial irreversibility. Samaniego and Sun (2019) analyze the long-run effects of vintage-specific investment subsidies in a vintage capital model.

<sup>8</sup>Restuccia and Rogerson (2008) and Hsieh and Klenow (2009) provide early contributions on the aggregate effects of capital misallocation across heterogeneous producers. David and Venkateswaran (2019) quantify the roles of different types of frictions, including financial ones, for capital misallocation.

<sup>9</sup>Ai, Bhandari, Chen, and Ying (2019) develop an optimal contracting model subject to agency frictions. The optimal allocation features dispersion in marginal products of capital across firms and can be implemented with state-contingent securities and collateral constraints.

we build a bridge between the quantitative literature on capital misallocation and the theoretical literature on efficiency in presence of pecuniary externalities. Thus, our results provide guidance for the design of second-best policies, such as investment subsidies.<sup>10</sup>

### 3 Capital Reallocation and Pecuniary Externalities

In this section, we describe a stylized model of capital reallocation with new and old capital. We analytically characterize the constrained efficiency of the allocation of capital in the presence of financial frictions that induce distributive and collateral externalities. We show that the distributive externality dominates the collateral externality; the price of old capital in stationary competitive equilibrium is too high from the perspective of efficiency. The economic intuition is as follows. The most financially constrained firms buy old capital due to its lower financing need; firms that buy new capital are less constrained or unconstrained, and while some of these firms benefit from a higher price of old capital, since they borrow against the resale value of their investment in terms of old capital, the severely constrained firms benefit from a lower price of old capital considerably more.

#### 3.1 Environment

Time is discrete and the horizon infinite, that is,  $t = 0, 1, 2, \dots$ . There is an infinitely-lived, risk-neutral representative household with preferences

$$\sum_{t=0}^{\infty} \beta^t C_t, \tag{1}$$

where  $\beta \in (0, 1)$  is the discount factor and  $C_t$  is consumption.

There are over-lapping generations of firms and the representative household owns all firms. At each date, a continuum of firms with measure one is born. Firms live at two dates, make an investment decision when young and produce when old. Each firm has access to a production function  $f$  with  $f(0) = 0$ ,  $f_k > 0$ , and  $f_{kk} < 0$ ; investing capital  $k_t > 0$  at date  $t$  yields output  $f(k_t)$  at date  $t + 1$ . Output can be used to make new capital goods and it takes one unit of output to make a unit of new capital goods. Capital goods are productive for two periods and then fully depreciate. We refer to capital goods with two periods of useful life as “new” capital (denoted  $k_t^N$ ) and to capital goods with a single residual period of productive life as “old” (denoted  $k_t^O$ ). New and old capital goods are perfect substitutes

---

<sup>10</sup>Relatedly, Gourio and Miao (2010) and Jo and Senga (2019) use quantitative models with heterogeneous firms to study the effects of dividend taxes and credit subsidies respectively.

in production and we define the total capital of a firm as  $k_t \equiv k_t^N + k_t^O$ .

### 3.2 Frictionless Economy and First Best

We start by considering a frictionless economy in which the representative household can choose investment in each firm without facing any financial frictions. We index firms of each generation by  $w \in \mathcal{W} = [w_{min}, w_{max}]$  with distribution  $\pi(w)$ .<sup>11</sup> The aggregate resource constraint for the frictionless economy is

$$\int f(k_{t-1}^N(w) + k_{t-1}^O(w)) d\pi(w) = C_t + \int k_t^N(w) d\pi(w); \quad (2)$$

aggregate output equals consumption of the representative household plus aggregate investment in new capital goods. Aggregate investment in new capital at date  $t - 1$  determines the aggregate stock of old capital at date  $t$

$$\int k_{t-1}^N(w) d\pi(w) = \int k_t^O(w) d\pi(w). \quad (3)$$

The first best (FB) allocation maximizes the utility of the representative household (1) by choosing aggregate consumption  $C_t$  and an allocation of new and old capital  $k_t^N(w)$  and  $k_t^O(w)$ ,  $\forall w \in \mathcal{W}$ , subject to the resource constraints (2) and (3), and taking as given  $k_{-1}^N(w)$  and  $k_{-1}^O(w)$ ,  $\forall w \in \mathcal{W}$ . The first-order conditions with respect to new and old capital satisfy

$$1 = \beta [f_k(k_t^{FB}) + q_{t+1}^{FB}] \quad (4)$$

$$q_t^{FB} = \beta f_k(k_t^{FB}), \quad (5)$$

where we use  $q_t^{FB}$  to denote the shadow value of old capital  $k_t^O$  in terms of date  $t$  consumption. Thus,  $q_t^{FB}$  can be interpreted as the first-best valuation (or price) of old capital. The economy is in steady state from date 1 onwards. Notice that the allocation of total capital is the same for all firms. By combining equations (4) and (5), we get that in a steady state  $q^{FB} = \frac{1}{1+\beta}$ , and the optimal scale of production for all firms is  $k^{FB} = f_k^{-1}\left(\frac{1}{\beta(1+\beta)}\right)$ . In the spirit of Jorgenson (1963), we can define the frictionless user cost of new and old capital as  $u_N^{FB} \equiv 1 - \beta q^{FB}$  and  $u_O^{FB} \equiv q^{FB}$ , and note that  $u_N^{FB} = u_O^{FB} \equiv u^{FB}$ . The user cost would be the rental rate in a frictionless rental market and we define it as of the beginning of the period. The allocation of new and old capital across firms is indeterminate, but must satisfy  $\int k_{t+1}^O(w) d\pi(w) = \int k_t^N(w) d\pi(w) = \frac{k^{FB}}{2}$ .

---

<sup>11</sup>We will later interpret  $w$  as the initial net worth of each firm.

### 3.3 Financial Frictions and Competitive Equilibrium

We now consider a competitive equilibrium with financial frictions. Firms are subject to the following financial frictions. Firms are born with exogenous net worth  $w$  distributed over the interval  $[w_{min}, w_{max}]$  according to an exogenous non-degenerate distribution  $\pi(w)$ , with  $0 < w_{min} < q^{FB}k^{FB}$  and  $k^{FB} < w_{max}$ , with positive mass in a neighborhood of  $w_{min}$  and  $w_{max}$ . We index firms by their net worth, but suppress the dependence on net worth wherever appropriate.

Firms can raise additional internal funds from the representative household, that is, issue equity by paying negative dividends  $d < 0$ , at a cost  $\phi(-d)$  incurred by the household, such that  $\phi(-d) = 0$  if  $d \geq 0$ ,  $\phi(-d) > 0$  if  $d < 0$ . We denote the marginal cost of equity issuance by  $\phi_d(-d) \equiv \frac{\partial \phi(-d)}{\partial (-d)}$  and assume it is positive, increasing, and convex. Specifically,  $\phi_d \geq 0$ ,  $\phi_d(0) = 0$  and  $\phi_{dd} \equiv \frac{\partial^2 \phi(-d)}{\partial (-d)^2} \geq 0$  (see, for example, Gomes, 2001).

Firms can also borrow from the representative household at rate  $R \equiv \beta^{-1}$ , but borrowing is subject to a collateral constraint. The collateral constraint requires that debt repayments cannot exceed a fraction  $\theta \in [0, 1)$  of the future resale value of new capital purchases. That is, the collateral value of new capital goods is the future price at which these can be sold as old capital next period. Old capital purchases have no future resale value, as old capital fully depreciates at the end of the period.<sup>12</sup> Rampini and Viswanathan (2010, 2013) show how to derive such collateral constraints in an economy with limited enforcement without exclusion, in which firms can default on their promises and retain their output, a fraction  $1 - \theta$  of their capital, as well as access to the markets for capital goods and financing.

Given their initial net worth  $w$  and the price of old capital  $q_t$ , firms maximize the present discounted value of their dividends net of equity issuance costs, that is, their value to the household, by choosing dividends  $d_{0t}$  and  $d_{1,t+1}$ , new and old capital  $k_t^N$  and  $k_t^O$ , and borrowing  $b_t$ , to solve

$$\max_{\{d_{0t}, d_{1,t+1}, b_t, k_t^N, k_t^O\} \in \mathbb{R}^3 \times \mathbb{R}_+^2} d_{0t} - \phi(-d_{0t}) + \beta d_{1,t+1} \quad (6)$$

subject to the budget constraints for current and next period,

$$w_{0t} + b_t = d_{0t} + k_t^N + q_t k_t^O \quad (7)$$

$$f(k_t^N + k_t^O) + q_{t+1} k_t^N = d_{1,t+1} + \beta^{-1} b_t, \quad (8)$$

---

<sup>12</sup>In Section 3.8 we consider a model with standard geometric depreciation, in which both new and old capital serve as collateral.

and the collateral constraint

$$\theta q_{t+1} k_t^N \geq \beta^{-1} b_t. \quad (9)$$

Denote the multipliers on the budget constraints by  $\mu_{0t}$  and  $\beta\mu_{1,t+1}$ , on the collateral constraint by  $\beta\lambda_t$ , and on non-negativity constraint for new and old capital by  $\underline{\nu}_t^N$  and  $\underline{\nu}_t^O$ , respectively. The optimal demand for new capital, old capital, and borrowing, as functions of initial net worth  $w$ , satisfy the following first-order conditions

$$1 + \phi_{d,t} = \beta [f_k(k_t) + q_{t+1}] + \beta\theta\lambda_t q_{t+1} + \underline{\nu}_t^N \quad (10)$$

$$q_t(1 + \phi_{d,t}) = \beta f_k(k_t) + \underline{\nu}_t^O \quad (11)$$

$$1 + \phi_{d,t} = 1 + \lambda_t, \quad (12)$$

where  $k_t = k_t^N + k_t^O$ . Moreover, the firm's marginal value of net worth at date  $t$  is  $\mu_{0,t} = 1 + \phi_{d,t} \geq 1$ , that is, equals one plus the marginal cost of raising additional equity. In contrast, the firm's marginal value of net worth at date  $t + 1$  is  $\mu_{1,t+1} = 1$ , as the firm pays out all its remaining net worth as dividends to the representative household when it exits. Finally, the premium on internal funds  $\phi_{d,t} = \lambda_t$ , that is, equals the multiplier on the collateral constraint.

A *stationary competitive equilibrium* is a set of policy functions mapping initial net worth to an allocation  $\{d_0(w), d_1(w), k^N(w), k^O(w), b(w)\}$ , that is, dividends, investment, and debt choices, and a price of old capital  $q$ , such that firms maximize the present discounted value of dividends net of equity issuance cost,  $\forall w \in \mathcal{W}$ , and the market for old capital clears, that is,  $\int k^N(w) d\pi(w) = \int k^O(w) d\pi(w)$ .

In a stationary equilibrium, the first-order conditions for new and old capital (10) and (11) can be written as investment Euler equations

$$1 \geq \beta \frac{1}{1 + \phi_d} \frac{f_k(k) + (1 - \theta)q}{\wp_N} \quad (13)$$

$$1 \geq \beta \frac{1}{1 + \phi_d} \frac{f_k(k)}{q} \quad (14)$$

with equality if  $k_N > 0$  and  $k_O > 0$ , respectively, where  $k = k_N + k_O$ , and we define the down payment per unit on new capital  $\wp_N \equiv 1 - \beta\theta q$ , that is, the price per unit of new capital minus the maximal amount the firm can borrow against the residual value next period, which is determined by the collateral constraint. Analogously, we can define the down payment on old capital as  $\wp_O \equiv q$ , as the firm cannot borrow against old capital. In

the spirit of Jorgenson (1963) we can rewrite (13) and (14) as

$$u_N(w) \equiv u_N + \phi_d \varphi_N = 1 - \beta q + \phi_d(1 - \beta \theta q) \geq \beta f_k(k) \quad (15)$$

$$u_O(w) \equiv u_O + \phi_d \varphi_O = q + \phi_d q \geq \beta f_k(k), \quad (16)$$

where  $u_N(w)$  ( $u_O(w)$ ) is the user cost of new (old) capital to a firm with net worth  $w$ . The choice between investment in new and old capital is determined by the trade-off between their user costs if the firm were unconstrained and their down payments.

Combining (13) and (14) we moreover have

$$1 = \beta \frac{1}{(1 + \phi_d)} \frac{(1 - \theta)q}{\varphi_N - \varphi_O} + \frac{(\underline{v}_N - \underline{v}_O)/(1 + \phi_d)}{\varphi_N - \varphi_O}. \quad (17)$$

If  $\varphi_N \leq \varphi_O$ , then (17) implies  $\underline{v}_O > 0$ , so no firm would buy old capital, which cannot be true in equilibrium. Therefore, in a stationary equilibrium,  $\varphi_N > \varphi_O$ , which means the down payment for new capital exceeds the down payment for old capital; equivalently,  $\frac{1}{1 + \beta \theta} > q$ .

But then (15) and (16) imply that  $u_N \leq u_O$ , as otherwise there would be no investment in new capital, which is not an equilibrium; equivalently,  $q \geq q^{FB}$ , that is, the price of old capital in competitive equilibrium weakly exceeds the price in a frictionless economy.

To interpret (17), define  $R_O \equiv \frac{(1 - \theta)q}{\varphi_N - \varphi_O}$ ; this can be interpreted as the shadow interest rate on the additional amount the firm can implicitly borrow by buying old capital instead of new capital. Since  $q \geq q^{FB}$ ,  $R_O \geq \beta^{-1}$ , that is, borrowing more by buying old capital is costly in equilibrium, and strictly so if  $q > q^{FB}$ .

Note that in the problem in (6) to (9) the objective is (weakly) concave and the constraint set (with constraints stated as inequality constraints) convex. Hence, the induced value function is weakly concave and, using the envelope condition, the marginal value  $1 + \phi_d$  weakly decreasing in  $w$ . Since  $u_O(w) - u_N(w) = u_O - u_N - \phi_d(\varphi_N - \varphi_O)$ , the difference in user costs between old and new capital is increasing in  $w$ . Old capital is relatively less costly for more financially constrained firms. This implies that in equilibrium, firms that are sufficiently constrained invest in only old capital, and firms shift to investing in new capital as their net worth increases. We stress that this equilibrium property of our model is consistent with the empirical evidence on capital reallocation (for example, Eisfeldt and Rampini, 2007, and Ma, Murfin, and Pratt, 2020).

In particular, dividend-paying firms have  $\phi_d = 0$ , so  $u_N(w) \leq u_O(w)$ , that is, prefer new capital at least weakly. Such firms invest  $\bar{k}$  which solves  $1 = \beta(f_k(k) + q)$ , where  $\bar{k} \geq k^{FB}$  with equality iff  $q = q^{FB}$ . Firms pay dividends if  $w \geq \bar{w} = \varphi_N \bar{k}$ . Firms that are indifferent between new and old capital must have  $\beta \frac{1}{1 + \phi_d} = R_O^{-1}$  (from (17)) and invest

$\underline{k}$ , which solves  $1 = R_O^{-1} \frac{f_k(k) + (1-\theta)q}{\varphi_N}$ , where  $\underline{k} \leq k^{FB}$  with equality iff  $q = q^{FB}$ . Firms are indifferent between new and old capital at the margin if  $w \in (\underline{w}_N, \bar{w}_O)$ , where  $\underline{w}_N = \underline{d}_0 + q\underline{k}$  and  $\bar{w}_O = \underline{d}_0 + \varphi_N \underline{k}$ ,  $\underline{d}_0 = 0$  if  $q = q^{FB}$ , and  $\underline{d}_0$  solves  $1 + \phi_d = \beta R_O$  if  $q > q^{FB}$ .

We summarize these results in the following proposition:

**Proposition 1 (Stationary Competitive Equilibrium Characterization)** *A stationary competitive equilibrium is characterized as follows:*

- (i) *New capital has a higher down payment than old capital ( $\varphi_N > \varphi_O$ ), but a (weakly) lower user cost from the perspective of an unconstrained firm ( $u_N \leq u_O$ ).*
- (ii) *The price of old capital (weakly) exceeds the price in a frictionless economy ( $q \geq q^{FB}$ ).*
- (iii) *If  $q > q^{FB}$ , there exist thresholds  $\underline{w}_N < \bar{w}_O < \bar{w}$  such that: firms with  $w \leq \underline{w}_N$  invest only in old capital; firms with  $w \in (\underline{w}_N, \bar{w}_O)$  invest  $\underline{k}$  and invest in both new and old capital; firms with  $w \geq \bar{w}_O$  invest only in new capital; and firms with net worth  $w \geq \bar{w}$  pay dividends and invest  $\bar{k} > k^{FB} > \underline{k}$ . If  $q = q^{FB}$ , there exists thresholds  $\underline{w}_N < \bar{w}_O = \bar{w}$  such that: firms with  $w \leq \underline{w}_N$  invest only in old capital; firms with  $w \geq \bar{w}_O$  invest  $k^{FB}$  and are indifferent between new and old capital at the margin; firms with  $w \in (\underline{w}_N, \bar{w}_O)$  invest a strictly positive minimum amount in old capital.*

We now compute a numerical example and use it to illustrate the main properties of the stationary competitive equilibrium. We assume the production function is  $f(k) = k^\alpha$  with  $\alpha \in (0, 1)$ . Net worth is uniformly distributed on  $[w_{min}, w_{max}]$ . The cost of equity issuance is a power function,  $\phi(-d) = \phi_0(-d)^{\phi_1}$  for  $d < 0$  and  $\phi(-d) = 0$  otherwise. The caption of Figure 1 reports all parameter values used in the example.

The stationary-equilibrium price of old capital associated with this parameterization is  $q = 0.511 > q^{FB} = 0.51$ . Figure 1 displays the policy functions for new capital (top left), old capital (top right), total capital, that is, the sum of new and old capital (bottom left), and the marginal cost of equity issuance (bottom right), in stationary equilibrium. Consistent with the characterization in Proposition 1, there are three thresholds  $\underline{w}_N < \bar{w}^O < \bar{w}$ , which we highlight with vertical lines in the figure. Firms with  $w < \underline{w}_N$  invest only in old capital. Their total investment increases in net worth, and their marginal cost of equity issuance decreases in net worth. Firms with  $\underline{w}_N < w < \bar{w}^O$  invest in both new and old capital, keeping the total investment  $\underline{k}$  constant, and issue a common level of equity, resulting in a constant marginal cost of equity issuance. Firms with  $\bar{w}^O < w < \bar{w}$  invest only in new capital, while still issuing equity. Firms with  $w > \bar{w}$  invest only in new capital and are unconstrained in their investment  $\bar{k}$ ; these firms pay dividends.

Figure 1: Stationary competitive equilibrium – example. Top left: new capital  $k^N$ ; top right: old capital  $k^O$ ; bottom left: total capital  $k$ ; bottom right: marginal cost of equity issuance  $\phi_d$ . The  $x$ -axes report net worth  $w$ . The parameter values are: discount rate  $\beta = 0.96$ ; support of net worth distribution  $w_{min} = 0.05$  and  $w_{max} = 1.5$ ; curvature of production function  $\alpha = 0.6$ ; collateralizability  $\theta = 0.5$ ; and cost of raising equity parameters  $\phi_0 = 0.1$  and  $\phi_1 = 2$ .

### 3.4 Constrained (In-)Efficiency

We now characterize the constrained-efficient allocation in this economy, that is, the allocation that arises if a benevolent planner with full commitment makes investment decisions on behalf of firms, subject to the same constraints that are present in the competitive equilibrium. We then use this characterization to analyze the nature of constrained inefficiency in competitive equilibrium.

Given an initial distribution of new and old capital,  $k_{-1}^N(w)$  and  $k_{-1}^O(w)$ , a planner maximizes the present discounted value of aggregate dividends net of costs of equity issuance (or, equivalently, aggregate consumption)

$$\int \left[ d_{10}(w) + \sum_{t=0}^{\infty} \beta^t (d_{0t}(w) - \phi(-d_{0t}(w)) + \beta d_{1,t+1}(w)) \right] d\pi(w), \quad (18)$$

subject to the budget constraints (7) and (8) with multipliers  $\beta^t \mu_{0,t}$  and  $\beta^{t+1} \mu_{1,t+1}$ , the collateral constraint (9) with multiplier  $\beta^{t+1} \lambda_t$ , the non-negativity constraints on new and old capital with multipliers  $\beta^t \underline{\nu}_t^N$  and  $\beta^t \underline{\nu}_t^O$ , and the market clearing condition for old capital (3) with multiplier  $\beta^t \eta_t$ .<sup>13</sup>

The first-order conditions with respect new and old capital are

$$1 + \phi_{d,t} = \beta [f_k(k_t) + q_{t+1}] + \beta \theta \lambda_t q_{t+1} + \underline{\nu}_t^N + \beta \eta_{t+1} \quad (19)$$

$$q_t(1 + \phi_{d,t}) + \eta_t = \beta f_k(k_t) + \underline{\nu}_t^O, \quad (20)$$

and with respect to debt (12). The first-order condition with respect to the price of old capital  $q_t$  for  $t = 1, 2, \dots$  is

$$\int k_t^O(w) (1 + \phi_{d,t}(w)) d\pi(w) = \int k_{t-1}^N(w) (1 + \theta \lambda_{t-1}(w)) d\pi(w). \quad (21)$$

The left-hand side of equation (21) reports the marginal effect of an increase in  $q_t$  on dividends of young firms at  $t$ , net of equity issuance costs. The right-hand side reports its marginal effect on the dividends of old firms at  $t$ , as well as its effect on collateral constraints at  $t - 1$ . In the absence of financial frictions, we would have  $\phi_{d,t}(w) = \lambda_{t-1}(w) = 0$ ; thus, equation (21) would coincide with the market-clearing condition for old capital (3), and the aggregate welfare effect of a marginal change in  $q_t$  would be zero. Thus, using the market clearing condition (3), we can simplify equation (21) to isolate the pecuniary externalities induced by the presence of financial frictions:

$$\int k_t^O(w) \phi_{d,t}(w) d\pi(w) = \theta \int k_{t-1}^N(w) \lambda_{t-1}(w) d\pi(w). \quad (22)$$

The left-hand side of equation (22) represents the aggregate distributive externality induced by a marginal increase in the price of old capital  $q_t$ : Firms that purchase old capital at  $t$  value the additional expenditure they need to incur as the product of the quantity purchased  $k_t^O$  and their marginal cost of equity issuance  $\phi_{d,t}$ .

The right-hand side of equation (22) represents the aggregate collateral externality induced by the same marginal increase in  $q_t$ : Firms that purchase new capital at  $t - 1$  and face a binding collateral constraint are able to borrow against a fraction  $\theta$  of the additional collateral value, and thus increase their investment; they value this benefit as the product of the additional collateral  $\theta k_{t-1}^N$  and the Lagrange multiplier on their collateral constraint  $\lambda_{t-1}$ .<sup>14</sup>

<sup>13</sup>We explicitly formulate the Lagrangian of this problem in Appendix A.1.

<sup>14</sup>The effect of the *current* price of old capital on *past* collateral constraints implies that the constrained-

Thus, a marginal increase in  $q_t$  induces a negative externality on the value of firms that issue equity to purchase old capital at  $t$ , and a positive externality on firms that purchase new capital at  $t - 1$  and are constrained in their borrowing. Equation (22) highlights that these two opposite externalities must offset each other in the constrained-efficient allocation.

Before proceeding to characterize the planning solution, we show that in the stationary competitive equilibrium, the aggregate distributive externality is larger than the aggregate collateral externality, resulting in an equilibrium price of old capital that is higher than the constrained-efficient one. Specifically, we prove that in stationary competitive equilibrium, we have

$$\int k^O(w)\phi_d(w)d\pi(w) > \theta \int k^N(w)\lambda(w)d\pi(w). \quad (23)$$

Let us start by considering the case  $q > q^{FB}$ . Using the characterization in Proposition 1, we know that  $k_N = 0$  for  $w < \underline{w}_N$ ,  $k_O = 0$  for  $w > \bar{w}_O$ , and  $\phi_d = 0$  for  $w > \bar{w}$ , with  $\underline{w}_N < \bar{w}_O < \bar{w}$ . Firms that are indifferent between new and old capital, that is, firms with  $w \in (\underline{w}_N, \bar{w}_O)$ , have the same (positive) marginal cost of equity, which we denote by  $\bar{\phi}_d$ .

As  $\phi_d$  is weakly decreasing in  $w$ , no firm purchasing old capital has a marginal value of net worth less than  $1 + \bar{\phi}_d$ , and no firm purchasing new capital has a marginal value of net worth larger than  $1 + \bar{\phi}_d$ . Formally, we have  $\phi_d \geq \bar{\phi}_d$  for  $w \leq \bar{w}_O$ , and  $\phi_d \leq \bar{\phi}_d$  for  $w \geq \underline{w}_N$ .

Furthermore, using the optimality condition for debt (12),  $\lambda(w) = \phi_d(w)$  and we can rewrite the right-hand-side of (23) as  $\theta \int k^N \phi_d d\pi$ . We can then bound the two integrals in (23) as follows:

$$\int k^O(w)\phi_d(w)d\pi(w) = \int^{\bar{w}_O} k^O(w)\phi_d(w)d\pi(w) \geq \bar{\phi}_d \int^{\bar{w}_O} k^O(w)d\pi(w), \quad (24)$$

and

$$\int k^N(w)\phi_d(w)d\pi(w) = \int_{\underline{w}_N}^{\bar{w}} k^N(w)\phi_d(w)d\pi(w) \leq \bar{\phi}_d \int_{\underline{w}_N}^{\bar{w}} k^N(w)d\pi(w). \quad (25)$$

Furthermore, the market-clearing condition for old capital (3), together with the characterization in Proposition 1, implies

$$\int_{\underline{w}_N}^{\bar{w}} k^N(w)d\pi(w) < \int^{\bar{w}_O} k^O(w)d\pi(w), \quad (26)$$

because the left-hand side of (26) is less than the aggregate supply of old capital in station-

---

efficient plan is time inconsistent. A planner without commitment, such as the one considered by Bianchi and Mendoza (2018), would disregard this effect. However, as we show below, even under our assumption of full commitment, the collateral externality is dominated by the distributive externality.

ary equilibrium, whereas the right-hand side represents aggregate demand for old capital.<sup>15</sup> Combining (24), (25), and (26), we have

$$\int k^O(w)\phi_d(w)d\pi(w) > \int k^N(w)\phi_d(w)d\pi(w). \quad (27)$$

Finally, as  $\theta < 1$ , we obtain the strict inequality in (23).<sup>16</sup>

Let us now consider the case  $q = q^{FB}$ . All firms investing in new capital, that is, with  $w > \underline{w}_N$ , are unconstrained. Thus their marginal cost of equity issuance is zero and we have  $\int k^O(w)\phi_d(w)d\pi(w) > 0 = \int k^N(w)\phi_d(w)d\pi(w)$ .

Hence, in stationary equilibrium, the aggregate distributive externality is larger than the aggregate collateral externality. By comparing this result with the constrained-efficiency condition for the price of old capital (22), we find that a marginal reduction in the price of old capital has a positive effect on aggregate welfare, implying that the competitive-equilibrium price is too high from the perspective of constrained efficiency.

We summarize this result in the following proposition:

**Proposition 2 (Sign of Constrained Inefficiency)** *In stationary competitive equilibrium, the aggregate distributive externality is larger than the aggregate collateral externality, that is,  $\int k^O(w)\phi_d(w)d\pi(w) > \theta \int k^N(w)\lambda(w)d\pi(w)$ . A marginal decrease in the price of old capital induces a positive welfare gain.*

### 3.5 Implementing First Best

We now characterize the stationary constrained-efficient allocation, and show that it achieves the first-best level of welfare in the stylized model. In stationary equilibrium, the optimality condition for the price of old capital (22) reads

$$\int k^O(w)\phi_d(w)d\pi(w) = \theta \int k^N(w)\lambda(w)d\pi(w).$$

---

<sup>15</sup>Inequality (26) is strict since we assume a positive mass of firms with  $w > \bar{w}$ .

<sup>16</sup>Notice that even if we were to assume a degenerate distribution of initial net worth, so that all young firms would be equally financially constrained, we would still conclude that the distributive externality between young and old firms dominates the collateral externality; in this case, inequality (27) would be an equality, and (23) would still be a strict inequality because  $\theta < 1$ . Importantly, this alternative model would still be a model with heterogeneity in the marginal value of net worth, specifically between young and old firms. However, this model would not generate the equilibrium sorting of firms into new and old investment observed in the empirical evidence on capital reallocation, because all firms would have the same composition of investment. We analyze the case of common net worth for young firms in a model with assets in fixed supply in Appendix OA.4, and show that the distributive externality dominates the collateral externality in that model, too. A model with an *infinitely-lived* representative firm, instead, would feature no distributive externality in stationary equilibrium, as we discuss in Section 3.9 and in more detail in Appendix OA.4.

Clearly, an allocation such that all firms pay non-negative dividends, that is,  $\phi_d = \lambda = 0$  for all  $w$ , satisfies this condition. We now show that the planner induces an allocation that achieves the first-best level of welfare and satisfies all budget and financial constraints, allowing all firms to be unconstrained and produce at the efficient scale  $k^{FB}$ . Imposing  $\phi_d = 0$  for all  $w$ , we can rewrite the optimality conditions (19) and (20) in stationary-equilibrium as follows:

$$1 = \beta (f_k(k^{FB}) + q^*) + \beta\eta \quad (28)$$

$$q^* + \eta = \beta f_k(k^{FB}), \quad (29)$$

where  $q^*$  is the stationary-equilibrium price of old capital in the constrained-efficient plan, and we have restricted attention to an allocation such that  $\underline{v}^N = \underline{v}^O = 0$  for all  $w$ .

Let  $q^* = \frac{w_{min}}{k^{FB}}$ . At this price, firms with the lowest level of initial net worth produce at the efficient scale, by investing entirely in old capital, without issuing equity:  $k^O(w_{min}) = k^{FB}$ . We need to ensure that the market for old capital clears at this price. To this end, consider the following allocation of new and old capital.

$$k^N(w) = \begin{cases} \frac{w - q^* k^{FB}}{1 - q^*(1 + \beta\theta)} & \text{if } w \leq k^{FB}(1 - \beta\theta q^*) \\ \bar{k}^N & \text{if } w > k^{FB}(1 - \beta\theta q^*) \end{cases} \quad (30)$$

and  $k^O(w) = k^{FB} - k^N(w)$ , with  $\bar{k}^N$  to be determined.

Given this allocation, we can write the market-clearing condition for old capital as follows:

$$\int^{k^{FB}(1 - \beta\theta q^*)} (k^{FB} - k^N(w)) d\pi(w) + (1 - \pi(k^{FB}(1 - \beta\theta q^*))) (k^{FB} - \bar{k}^N) = \int^{k^{FB}(1 - \beta\theta q^*)} k^N(w) d\pi(w) + (1 - \pi(k^{FB}(1 - \beta\theta q^*))) \bar{k}^N, \quad (31)$$

where the left-hand side represents aggregate demand for old capital and the right-hand side represents aggregate demand for new capital, which in stationary equilibrium coincides with the aggregate supply of old capital. Equation (31) can be solved to find the value for  $\bar{k}^N$  that guarantees market clearing.<sup>17</sup>

We now present an implementation of the constrained efficient allocation. The planner's allocation can be decentralized as a competitive equilibrium with proportional taxes

---

<sup>17</sup>A sufficient condition for the solution to be in the interval  $[0, k^{FB}]$  is that there is a sufficiently large mass of firms with initial net worth larger than  $k^{FB}$ . If  $\pi$  is uniform, as in our numerical example,  $w_{max} \geq k^{FB}$  is sufficient.

at rates  $\tau^N$  and  $\tau^O$  on new and old capital respectively. These taxes are offset by lump-sum transfers to each firm, in order not to redistribute resources across firms. Tax rates and transfers can be firm specific, that is, are functions of net worth  $w$ . With this implementation, the budget constraint of a newborn firm with initial net worth  $w$  becomes

$$w + b_t + T_t = d_{0t} + k_t^N(1 + \tau_t^N) + q_t k_t^O(1 + \tau_t^O)$$

with a lump-sum transfer  $T_t = \tau_t^N k_t^N + \tau_t^O q_t k_t^O$ .

By inspection of equations (28) and (29), we see that the tax rates that implement the first-best stationary equilibrium are

$$\tau^N = -\beta\eta = -\beta(q^{FB} - q^*)$$

and

$$\tau^O = \frac{\eta}{q^*} = \frac{q^{FB}}{q^*} - 1.$$

As  $\eta = \beta f'(k^{FB}) - q^* > 0$ , that is, old capital is scarce from the perspective of the planner, we have  $\tau^N < 0$  and  $\tau^O > 0$ . The planner internalizes the distributive externalities in the market for old capital and induces a price of old capital sufficiently low that all firms can afford the optimal production scale without incurring equity issuance costs. The optimal policy that supports this allocation is a subsidy on new capital, which increases the future supply of old capital, combined with a tax on old capital, which ensures the first-best production scale is optimal given the low price of old capital required to undo the effects of financial frictions. It might seem counterintuitive that the planner taxes old capital, given the objective to make it cheaper. However, recall that these taxes are rebated in a lump-sum fashion to each agent. Thus, a tax on old capital has only a positive effect on buyers of old capital, that is, constrained firms, because it allows the planner to reduce the price they face. Indeed, the larger the reduction in price required relative to the first-best price  $q^{FB}$ , the larger is the optimal tax  $\tau^O$ . Notice that both tax rates  $\tau^N$  and  $\tau^O$  are constant and independent of firms' net worth, whereas they are offset by lump-sum taxes or transfers that vary with firms' net worth, because of heterogeneity in the composition of investment between new and old capital.

We consider again our numerical example and solve for the constrained-efficient allocation. In Figure 2, we illustrate the stationary competitive equilibrium (solid lines) as before, and contrast it with the constrained-efficient allocation rule that supports the first-best outcome described in equation (30) (dashed lines). While total capital (bottom left) is weakly increasing in net worth in competitive equilibrium, inducing inefficient dispersion in marginal products, the constrained-efficient allocation equalizes the scale of produc-

Figure 2: Stationary competitive equilibrium and constrained-efficient allocation – example. Top left: new capital  $k^N$ ; top right: old capital  $k^O$ ; bottom left: total capital  $k$ ; bottom right: marginal cost of equity issuance  $\phi_d$ . The  $x$ -axes report net worth  $w$ . Solid lines denote the competitive-equilibrium allocation, dashed lines the constrained-efficient allocation. See the caption of Figure 1 for the parameter values.

tion across all firms, increasing aggregate investment and reallocating old capital towards the most constrained firms, without incurring any equity issuance costs (bottom right). The constrained-efficient allocation induces the first-best outcome with equilibrium price  $q^* = 0.037$ . The tax rates that decentralize this outcome are  $\tau^N = -0.454$  and  $\tau^O = 12.819$ .

In Online Appendix OA.1, we consider the case in which the planner faces the additional constraint that purchases of old capital cannot be distorted. The planner makes investment decisions on behalf of firms, taking each firm’s Euler equation for old capital as a constraint. Equivalently, the planner chooses proportional taxes on new capital, rebated lump-sum to each firm, but cannot tax old capital. In this case, the planner cannot implement the first-best allocation. However, the optimal policy is still a subsidy on new capital. We also solve for the constrained-efficient allocation in this case in our numerical example.

### 3.6 Risk-Averse Entrepreneurs

In our stylized model, firms maximize the present discounted value of dividends net of equity issuance cost, and the planner maximizes consumption of an infinitely-lived representative household who consumes aggregate dividends. We now consider the case in which firms are owned by over-lapping generations of risk-averse entrepreneurs, whose individual consumption coincides with dividends from their own firm.

Specifically, entrepreneurs maximize  $u(c_{0t}) + \beta u(c_{1,t+1})$ , where  $u$  is a utility function, with  $u_c > 0$ ,  $u_{cc} < 0$ ,  $\lim_{c \rightarrow 0} u_c(c) = +\infty$ , and entrepreneurial consumption coincides with dividends, which satisfy the budget constraints (7) and (8). We discuss this version of the model in detail in Online Appendix OA.2.

A utilitarian planner maximizes the present discounted value of utilities of all (present and future) entrepreneurs. The (stationary) constrained-efficient price of old capital satisfies the following optimality condition:

$$\int k^O(w) u_c(c_0(w)) d\pi(w) = \int k^N(w) [u_c(c_1(w)) + \theta\lambda(w)] d\pi(w),$$

where the left-hand side and the first term in the sum on the right-hand side represent the distributive externalities on buyers and sellers of old capital, respectively, whereas the second term on the right-hand side represents the collateral externality.

In this model, the marginal value of entrepreneurial net worth equals the marginal utility of consumption, which is strictly decreasing in net worth, in contrast to the marginal equity issuance cost in the baseline model, which is equal to a positive constant in the indifference region between new and old capital, and equal to zero for unconstrained firms. Despite this difference, the fact that the marginal utility of consumption is decreasing implies that the planner still wants to induce a lower price of old capital than in competitive equilibrium, in order to redistribute resources toward more financially constrained entrepreneurs, who are net buyers of old capital in equilibrium. Hence, our result on the sign of constrained inefficiency obtains also with risk-averse entrepreneurs. We now state this result formally and prove it in Online Appendix OA.2.<sup>18</sup>

#### Proposition 3 (Sign of Constrained Inefficiency – Risk-Averse Entrepreneurs)

*Assume that in stationary equilibrium  $q > q^{FB}$ . Then, the aggregate distributive externality exceeds the aggregate collateral externality, that is*

$$\int k^O(w) u_c(c_0(w)) d\pi(w) > \int k^N(w) [u_c(c_1(w)) + \theta\lambda(w)] d\pi(w).$$

---

<sup>18</sup>While the proposition focuses on the case  $q > q^{FB}$ , Online Appendix OA.2 provides a weak condition under which the same result obtains when  $q = q^{FB}$ .

*A marginal decrease in the price of old capital induces a positive welfare gain.*

### 3.7 Heterogeneity in Productivity

In our baseline model, firms are heterogeneous only in their initial net worth. We now extend this framework to allow for heterogeneity in productivity and show that our main efficiency result obtains in this richer model. At their initial date, firms draw initial net worth  $w$  and a level of productivity  $s \in \mathcal{S} \equiv \{s_1, \dots, s_N\}$  from a joint distribution  $\pi(w, s)$ . At the production date, firms produce output with production function  $y_t = sf(k_t)$ . We discuss this model in detail in Online Appendix [OA.3](#).

Allocations in stationary equilibrium are functions of  $(w, s)$ , and the preference for new vs. old capital is thus tied to both net worth and productivity. Crucially, we show the marginal equity issuance cost is (weakly) increasing in productivity:  $\frac{\partial \phi_d(w, s)}{\partial s} \geq 0$ . Thus, firms with lower net worth and higher productivity tend to prefer old capital, whereas less financially constrained firms, that is, firms with higher net worth and lower productivity tend to purchase new capital. The market for old capital reallocates capital from less productive to more productive firms.

The (stationary) constrained-efficient price of old capital satisfies the following optimality condition:

$$\int k^O(w, s) \phi_d(w, s) d\pi(w, s) = \theta \int k^N(w, s) \lambda(w, s) d\pi(w, s),$$

where the left-hand side represents the aggregate distributive externality from a marginal change in the price of old capital, and the right-hand side represents the aggregate collateral externality.

In competitive equilibrium, we show that all firms that are indifferent between new and old capital have the same marginal value of net worth, independent of their productivity. This feature allows us to generalize our main efficiency result also to the case with heterogeneous productivity. We now state this result formally and prove it in Online Appendix [OA.3](#).

**Proposition 4 (Sign of Constrained Inefficiency – Heterogeneity in Productivity)**

*In the stationary competitive equilibrium, the aggregate distributive externality exceeds the aggregate collateral externality, that is,*

$$\int k^O(w, s) \phi_d(w, s) d\pi(w, s) > \theta \int k^N(w, s) \lambda(w, s) d\pi(w, s).$$

*A marginal decrease in the price of old capital induces a positive welfare gain.*

### 3.8 Firm Life Cycle and Long-Lived Capital

In our stylized model, firms live for two dates and capital is productive for two periods. The assumption that firms live for only one period rules out endogenous net worth dynamics. The assumption that capital is unproductive after two dates rules out the possibility of using old capital as collateral. We now show that our main result on the sign of inefficiency in competitive equilibrium obtains in a more general version of the model in which firms have a stochastic life cycle and capital is long lived.

To this end, we generalize the model in two ways. First, firms follow a stochastic life cycle. Specifically, at each date, with exogenous probability  $\rho \in (0, 1]$ , firms learn that they will die after producing and paying their remaining net worth as a dividend. With probability  $1 - \rho$ , firms continue their activity. Thus, as long as  $\rho < 1$ , firm net worth evolves endogenously. At each date, a measure  $\rho$  of new firms is born with initial net worth drawn from an exogenous distribution  $\pi_0(w_0)$ . The stationary distribution of net worth  $\pi(w)$ , however, is an equilibrium object.

Second, capital goods depreciate as follows. For each unit of new capital, a fraction  $\delta^N \in (0, 1]$  becomes old after production. Old capital depreciates at geometric rate  $\delta^O \in (0, 1]$  each period. With these assumption, firms can pledge a fraction  $\theta$  of the resale value of capital next period  $(1 - \delta^N(1 - q_{t+1}))k_t^N + q_{t+1}(1 - \delta^O)k_t^O$  as collateral. Hence, both new and old capital serve as collateral. This environment nests the baseline model, which can be recovered by setting  $\rho = \delta^N = \delta^O = 1$ . Furthermore, it also nests a model in which all new investment is transformed into a homogenous type of capital after one period; this model can be recovered by setting  $\delta^N = 1$  and  $\delta^O = \delta \in (0, 1)$ .

We analyze this model in Appendix A.2. Here, we state our main result on constrained inefficiency. We introduce the following notation. We denote firm age by  $a = 0, 1, \dots$  and the mass of age  $a$  firms that survive into the next period by  $\gamma_a \equiv \rho(1 - \rho)^a$ . The (stationary) constrained-efficient price of old capital satisfies the following optimality condition:

$$\int \sum_{a=0}^{\infty} \gamma_a [k_a^O \phi_{d,a} - (\delta^N k_a^N + (1 - \delta^O)k_a^O) (1 - \rho)\phi_{d,a+1}] d\pi_0(w_0) = \theta \int \sum_{a=0}^{\infty} \gamma_a \lambda_a (\delta^N k_a^N + (1 - \delta^O)k_a^O) d\pi_0(w_0), \quad (32)$$

where the left-hand side represents the aggregate distributive externality from a marginal change in the price of old capital and the right-hand side the aggregate collateral externality.

Different from the stylized model without firm life cycle, the marginal value of net worth is no longer necessarily constant in the indifference region between new and old capital.

Moreover, old capital also serves as collateral, thus inducing a richer set of externalities from the price of old capital. Despite these differences with our baseline case, we can show that our result on the sign of the constrained inefficiency generalizes also to this environment. The economic intuition is that the more constrained firms are net buyers of old capital; although reducing the price of old capital decreases its collateral value, this effect is dominated by the distributive effect of making old capital cheaper for these firms. We now state this result, which we prove in Appendix A.2, formally.

**Proposition 5 (Sign of Constrained Inefficiency – Long-Lived Firms and Capital)**

*In the stationary competitive equilibrium, the aggregate distributive externality exceeds the aggregate collateral externality, that is, the left-hand side of (32) is strictly larger than the right-hand side. A marginal decrease in the price of old capital induces a positive welfare gain.*

### 3.9 Essential Role of Heterogeneity and Reallocation

Our results show that the distributive externality exceeds the collateral externality in stationary competitive equilibrium under quite general conditions, including with risk-neutral firms and costly equity issuance, entrepreneurial risk aversion, heterogeneity in productivity, and long-lived firms and capital. We now discuss the essential role of heterogeneity and equilibrium reallocation for this result, and compare our insights with the related literature on collateral constraints that depend on asset prices.

As Dávila and Korinek (2018) show in a two-period model, distributive externalities arise because of two features: (i) heterogeneity in the marginal valuation of resources, due to market incompleteness; and (ii) non-zero net asset trading, i.e., in our context, a positive volume of capital reallocation in stationary equilibrium. Our assumption that there are over-lapping generations of firms subject to financing costs induces both (i) heterogeneity in the marginal value of net worth – among firms of different age, as well as among firms of the same age, but with different levels of net worth or productivity – and (ii) positive capital reallocation, that is, trade in old capital, in stationary equilibrium, because younger and more productive firms purchase old capital from older firms. In the quantitative model of Section 4, we also obtain heterogeneity in the marginal value of net worth and reallocation of old capital due to idiosyncratic productivity shocks.

When there are both collateral and distributive externalities, it is in general not possible to sign the net effects of asset prices on welfare (Dávila and Korinek, 2018). Nevertheless, in the class of infinite-horizon models we consider, we obtain an unambiguous result. Given our formulation of the collateral constraint that depends linearly on the resale value of

capital (Kiyotaki and Moore, 1997; Rampini and Viswanathan, 2010, 2013), the firm optimality condition with respect to debt imposes a tight link between the collateral externality and the distributive externality in stationary equilibrium. For instance, in the model of Section 3.4 we could express the collateral externality for a firm with net worth  $w$  as  $\theta\lambda(w)k^N(w) = \theta\phi_d(w)k^N(w)$  using equation (12) and exploiting stationarity. Thus, the comparison of aggregate distributive and collateral externalities reduces to a comparison of the covariance between the marginal value of net worth and purchases of old capital and the covariance between the marginal value of net worth and purchases of new capital. Furthermore, in stationary equilibrium, aggregate purchases of new capital coincide with aggregate sales of old capital, by market clearing. Because of equilibrium sorting of more constrained firms into old capital, the former covariance is larger than the latter, delivering our result on the sign of the inefficiency.

This insight generalizes to the case in which the marginal value of net worth is the marginal utility of consumption, the case in which the marginal value of net worth depends on productivity, as well as the case in which both new and old capital serve as collateral, and the distribution of net worth is endogenous.

To further highlight the essential role of heterogeneity and reallocation, we can compare our model with models that feature an infinitely-lived representative entrepreneur and ex-ante heterogeneity between the impatient representative entrepreneur and a patient lender as in Kiyotaki and Moore (1997) or a representative entrepreneur in a small open economy. In these models, there are no distributive externalities in stationary equilibrium, because the representative entrepreneur must keep a constant amount of capital (or land), by definition of stationary equilibrium, implying that there is no equilibrium reallocation.<sup>19</sup> Thus, these models can only feature collateral externalities in stationary equilibrium.

To show this formally, we analyze the connection between our results and the large literature on models with a representative entrepreneur and assets in fixed supply further in Appendix OA.4. Specifically, we first consider a model with a representative entrepreneur and land and show that lack of reallocation in stationary equilibrium implies that there is only a collateral externality, which is closely related to the effects of asset-price changes analyzed by Kiyotaki and Moore (1997). Next, we consider a version of the same model, but with over-lapping generations of entrepreneurs; this modification implies heterogeneity among entrepreneurs and positive reallocation in stationary equilibrium and thus distributive externalities. We show that the distributive externality dominates the collateral externality in this model, when the discount factor equals the inverse of the equilibrium interest rate. We also analyze the role of entrepreneurial impatience for pecuniary externalities.

---

<sup>19</sup>Even if lender and entrepreneur have different marginal values of net worth, they do not trade capital in stationary equilibrium.

## 4 Quantitative Model

We now consider a quantitative model of investment and capital reallocation with a stochastic firm life cycle, long-lived capital, and persistent idiosyncratic productivity shocks. In this model, both financial frictions and stochastic productivity are drivers of capital reallocation. We calibrate this model to analyze efficiency quantitatively in Section 5.

### 4.1 Environment

Time is discrete and infinite. As in the model of Section 3, a representative household with linear utility and discount factor  $\beta$  owns all firms in the economy. In every period, a continuum of measure  $\rho$  of firms are born and receive a common initial endowment of output  $w_0$  from the household.<sup>20</sup> Firm  $i$  at time  $t$  produces output  $y_{it}$  combining new and old capital goods  $k_{i,t-1}^N$  and  $k_{i,t-1}^O$ , subject to idiosyncratic productivity shocks  $s_{it}$  with the following technology

$$y_{it} = s_{it}f(k_{i,t-1}), \quad (33)$$

with  $f_k > 0$ ,  $f_{kk} < 0$ ,  $k_{i,t-1} \equiv g(k_{i,t-1}^N, k_{i,t-1}^O)$ , where  $g$  is a constant returns to scale bundle of new and old capital, with  $g_N, g_O > 0$ ,  $g_{NN}, g_{OO} \leq 0$ , and subscripts denote first and second partial derivatives with respect to new (N) and old (O) capital, respectively. We assume that new and old capital are imperfect substitutes in the quantitative model, because this is empirically plausible and facilitates the computation by avoiding corner solutions.

As in the model of Section 3.8, firms die with probability  $\rho$  at the end of each period. Dying firms produce output and then distribute their new worth as a dividend. We denote age by  $a$  and let  $s^a$  be a history of realizations of idiosyncratic shocks up to firm age  $a$ , with associated exogenous probability  $p(s^a)$ . The measure of firms of age  $a$  that survive and invest to produce in the following period is  $\gamma_a = \rho(1 - \rho)^a$ .

Output can be consumed by the household or transformed into new capital with constant unit marginal cost. Investment requires one period of time to build. A fraction  $\delta^N$  of each unit of new capital becomes old in the following period. A fraction  $\delta^O$  of each unit of old capital becomes useless in the following period. Firms can also scrap old capital and recover  $\underline{q} \geq 0$  units of output. This assumption is empirically plausible and imposes a lower bound on the price of old capital that the planner can induce. We assume  $\underline{q}$  is sufficiently low that no capital is scrapped either in the first-best allocation or in equilibrium.

---

<sup>20</sup>Heterogeneity in net worth arises endogenously because of productivity shocks and net worth accumulation. Thus, for simplicity, we abstract from initial heterogeneity.

## 4.2 Frictionless Economy and First Best

The aggregate resource constraint of the frictionless economy is

$$\sum_{a=0}^{\infty} \gamma_a \sum_{s^{a+1}} p(s^{a+1}) [s_{a+1} f(g(k_{t-1}^N(s^a), k_{t-1}^O(s^a))) + (1 - \delta^N) k_{t-1}^N(s^a)] = C_t + \sum_{a=0}^{\infty} \gamma_a \sum_{s^a} p(s^a) k_t^N(s^a), \quad (34)$$

where the left-hand side is aggregate output and undepreciated new capital, and the right-hand side is consumption of the representative household and aggregate new capital. The evolution of the stock of old capital satisfies

$$\sum_{a=0}^{\infty} \gamma_a \sum_{s^a} p(s^a) [\delta^N k_{t-1}^N(s^a) + (1 - \delta^O) k_{t-1}^O(s^a)] = \sum_{a=0}^{\infty} \gamma_a \sum_{s^a} p(s^a) k_t^O(s^a), \quad (35)$$

where the left-hand side is the sum of depreciated new capital and undepreciated old capital from the previous period, that is, the aggregate supply of old capital, and the right-hand side is the aggregate demand for old capital.

The first-best allocation maximizes the utility of the representative household (1) subject to the resource constraints (34) and (35). The optimality conditions for new and old capital are

$$1 = \beta \mathbb{E}_t [s_{a+1} f_k(k_t^{FB}(s^a)) g_{N,t}(s^a) + (1 - \delta^N)(1 - q_{t+1}^{FB})] \quad (36)$$

$$q_t^{FB} = \beta \mathbb{E}_t [s_{a+1} f_k(k_t^{FB}(s^a)) g_{O,t}(s^a) + (1 - \delta^O) q_{t+1}^{FB}], \quad (37)$$

where  $\mathbb{E}_t$  denotes the expectation conditional on information at date  $t$ ,  $q_t^{FB}$  denotes the first-best valuation of old capital, and we use shorthand notation  $g_{N,t}(s^a)$  and  $g_{O,t}(s^a)$  to denote the marginal effect of investment in new and old capital on total capital in production, that is,  $g_N(k_t^N(s^a), k_t^O(s^a))$  and  $g_O(k_t^N(s^a), k_t^O(s^a))$ , respectively.

In the stationary First-Best allocation, the efficient value of old capital is

$$q^{FB} = \frac{1 - \beta(1 - \delta^N)}{1 + \beta\delta^N - \beta(1 - \delta^O)}, \quad (38)$$

and the allocation of capital satisfies

$$k^{FB}(s^a) = f_k^{-1} \left( \frac{1 - \beta(1 - \delta^N)(1 - q^{FB})}{\beta \mathbb{E} [s_{a+1} | s^a]} \right). \quad (39)$$

Unlike in the stylized model, when new and old capital are imperfect substitutes, equations (36) and (37) determine a unique allocation of new and old capital for all firms.

### 4.3 Financial Frictions and Competitive Equilibrium

We now consider the competitive equilibrium in the presence of financial frictions. As in the stylized model, firms can raise external funds in two ways. First, they can issue equity, subject to a twice differentiable, convex equity issuance cost  $\phi$ . This cost is zero if firms pay a non-negative dividend. Second, they can issue non-contingent debt, subject to a collateral constraint, which specifies that the promised repayment cannot exceed a fraction  $\theta$  of the total resale value of new and old capital in the following period.

The expected present discounted value of dividends, net of equity issuance costs, of a firm born at time  $t$  is

$$\sum_{a=0}^{\infty} \beta^a \gamma_a \sum_{s^a} p(s^a) [(d_{t+a}(s^a) - \phi(-d_{t+a}(s^a)))] + \sum_{a=1}^{\infty} \beta^a \gamma_{a-1} \rho \sum_{s^a} p(s^a) w_{t+a}(s^a), \quad (40)$$

where  $d_t(s^a)$  are dividends of continuing firms and  $w_t(s^a)$  is net worth, which is paid as a dividend by dying firms. The dividend of a continuing firm satisfies the following budget constraint:

$$d_t(s^a) = w_t(s^a) + b_t(s^a) - k_t^N(s^a) - q_t k_t^O(s^a), \quad (41)$$

where  $q_t$  is the price of old capital and  $b_t(s^a)$  is non-contingent debt, with gross interest rate  $\beta^{-1}$ . Firm net worth evolves as follows. All firms are born with  $w_t(s^0) = w_0$ . For  $a = 1, 2, \dots$ , we have

$$w_t(s^a) = s_a f(k_{t-1}(s^{a-1})) + (1 - \delta^N(1 - q_t))k_{t-1}^N(s^{a-1}) + q_t(1 - \delta^O)k_{t-1}^O(s^{a-1}) - \beta^{-1}b_{t-1}(s^{a-1}) \quad (42)$$

and total capital in production is given by a bundle of new and old capital,

$$k_{t-1}(s^{a-1}) = g(k_{t-1}^N(s^{a-1}), k_{t-1}^O(s^{a-1})). \quad (43)$$

Firms face a collateral constraint, which states that debt cannot exceed a fraction  $\theta$  of the resale value of new and old capital:

$$\theta [(1 - \delta^N(1 - q_{t+1}))k_t^N(s^a) + q_{t+1}(1 - \delta^O)k_t^O(s^a)] \geq \beta^{-1}b_t(s^a). \quad (44)$$

The square bracket on the left-hand side of equation (44) reports the value of collateral, which consists of undepreciated new capital, depreciated new capital that is transformed into old capital, and undepreciated old capital.

We denote by  $\beta^{t+1}\lambda_t(s^a)$  the multiplier on the collateral constraint and  $\phi_{d,t}(s^a)$  the marginal equity issuance cost. The firm optimality conditions for new capital, old capital,

and debt, are

$$1 + \phi_{d,t}(s^a) = \beta \mathbb{E}_t [s_{a+1} f_k(k_t(s^a)) g_{N,t}(s^a) + (1 - \delta^N (1 - q_{t+1}))] (1 + (1 - \rho) \phi_{d,t+1}(s^{a+1})) + \beta \theta \lambda_t(s^a) (1 - \delta^N (1 - q_{t+1})) \quad (45)$$

$$q_t (1 + \phi_{d,t}(s^a)) = \beta \mathbb{E}_t [s_{a+1} f_k(k_t(s^a)) g_{O,t}(s^a) + (1 - \delta^O) q_{t+1}] (1 + (1 - \rho) \phi_{d,t+1}(s^{a+1})) + \beta \theta \lambda_t(s^a) (1 - \delta^O) q_{t+1} \quad (46)$$

$$\phi_{d,t}(s^a) = (1 - \rho) \mathbb{E}_t \phi_{d,t+1}(s^{a+1}) + \lambda_t(s^a). \quad (47)$$

We highlight some important differences between these optimality conditions and their counterparts in the stylized model, that is, equations (10), (11), (12). First, productivity is stochastic, implying that both future marginal products and future marginal equity issuance costs are also stochastic. Moreover, we assume that markets are incomplete and firms issue noncontingent debt. Thus, all three optimality conditions (45), (46), and (47) involve the conditional-expectation operator  $\mathbb{E}_t$ . Second, both new and old capital are long lived, and both serve as collateral. Thus, equation (46) equates the marginal cost of investing in old capital, on the left-hand side, with the marginal benefit, which depends on the future marginal product, as well as the future resale value, and the effect of old capital on the collateral constraint.

In equilibrium, the price of old capital  $q_t$  satisfies the market-clearing condition (35).

#### 4.4 Constrained Efficiency

We now consider the problem of a planner who chooses investment in new and old capital, as well as debt, on behalf of individual firms, under the same set of constraints and frictions, but internalizing the effects of these choices on the price of old capital. This problem is equivalent to the problem of a Ramsey planner who chooses firm-specific proportional taxes on new and old capital and rebates them in a lump-sum fashion to each firm.

The planner maximizes the present discounted value of aggregate dividends

$$\sum_{t=0}^{\infty} \beta^t \left[ \sum_{a=0}^{\infty} \sum_{s^a} p(s^a) \gamma_a [(d_t(s^a) - \phi(-d_t(s^a)))] + \sum_{a=1}^{\infty} \sum_{s^a} p(s^a) \gamma_{a-1} \rho w_t(s^a) \right] \quad (48)$$

subject to firms' budget constraints, collateral constraints, with multiplier  $\beta^{t+1} \lambda_t(s^a)$ , and the market-clearing condition (35), with multiplier  $\beta^t \eta_t$ . Furthermore, the planner must induce a price of old capital that is weakly larger than the scrap value. We denote the multiplier on this constraint by  $\beta^t \zeta_t$ .

The optimality conditions for new capital, old capital, and debt, are

$$1 + \phi_{d,t}(s^a) = \beta \mathbb{E}_t [s_{a+1} f_k(k_t(s^a)) g_{N,t}(s^a) + (1 - \delta^N (1 - q_{t+1}))] (1 + (1 - \rho) \phi_{d,t+1}(s^{a+1})) + \beta \theta \lambda_t(s^a) (1 - \delta^N (1 - q_{t+1})) + \beta \delta^N \eta_{t+1} \quad (49)$$

$$q_t (1 + \phi_{d,t}(s^a)) = \beta \mathbb{E}_t [s_{a+1} f_k(k_t(s^a)) g_{O,t}(s^a) + (1 - \delta^O) q_{t+1}] (1 + (1 - \rho) \phi_{d,t+1}(s^{a+1})) + \beta \theta (1 - \delta^O) \lambda_t(s^a) q_{t+1} - \eta_t + \beta (1 - \delta^O) \eta_{t+1}, \quad (50)$$

and (47). When choosing new and old capital, the planner takes into account the effect of these investment decisions on the resource constraint for old capital, and thus on its price. In particular, an additional unit of new capital leads to  $\delta^N$  additional units of supply of old capital in the following period. In a similar fashion, demand for old capital draws from the current stock, and adds  $(1 - \delta^O)$  units to the future stock. The terms involving the multipliers  $\eta_t$  and  $\eta_{t+1}$  in equations (49) and (50) internalize these effects.

The optimality condition for the price of old capital is

$$\sum_{a=0}^{\infty} \gamma_a \sum_{s^a} p(s^a) k_t^O(s^a) (1 + \phi_{d,t}(s^a)) = \sum_{a=0}^{\infty} \gamma_a \sum_{s^{a+1}} p(s^{a+1}) [\delta^N k_{t-1}^N(s^a) + (1 - \delta^O) k_{t-1}^O(s^a)] (1 + (1 - \rho) \phi_{d,t}(s^{a+1}) + \theta \lambda_{t-1}(s^a)) + \zeta_t. \quad (51)$$

The sum on the left-hand side of equation (51) represents the marginal cost of increasing the price  $q_t$  for firms that purchase old capital. The sum on the right-hand side represents the marginal benefit of increasing net worth for firms that own old capital, as well as the marginal effect of  $q_t$  on the borrowing capacity of constrained firms at  $t - 1$ . Thus, as long as the scrappage-value constraint is not binding, the planner sets the net effect of distributive and collateral externalities equal to zero.

We also consider the case in which the planner faces the additional constraint that purchases of old capital cannot be distorted (analogous to the version of the stylized model in Online Appendix OA.1). We assume that the planner can only choose the amount of new capital used in production on behalf of firms, and takes as a constraint their demand for old capital. In the interest of brevity, we relegate the derivation of the optimality conditions to Online Appendix OA.5. Furthermore, in Online Appendix OA.6, we describe our solution method for the stationary constrained-efficient allocation.

## 5 Calibration and Quantitative Analysis

In this section, we calibrate the model with idiosyncratic productivity shocks. We then provide a quantitative analysis of inefficiency in competitive equilibrium and compare the stationary equilibrium with the constrained-efficient allocation.

### 5.1 Calibration

We now describe our choices of parameter values, which we report in Table 1. A period in the model coincides with a year, and we thus set  $\beta = 0.96$ . We make the following assumptions about functional forms. The production function is  $f(k) = k^\alpha$  with  $\alpha \in (0, 1)$ . We set  $\alpha = 0.6$  to reflect a typical value for the capital share in the literature on firm dynamics, adjusted to account for the choice of labor input, which we abstract from modelling.<sup>21</sup>

Firms combine new and old capital in a CES bundle  $g(k^N, k^O) = [(\sigma^N)^{\frac{1}{\epsilon}}(k^N)^{\frac{\epsilon-1}{\epsilon}} + (1 - \sigma^N)^{\frac{1}{\epsilon}}(k^O)^{\frac{\epsilon-1}{\epsilon}}]^{\frac{\epsilon}{\epsilon-1}}$ . In our stylized model, we assumed perfect substitutability between new and old capital. We use the quantitative model to show that the key insights are robust to a plausible degree of imperfect substitutability. We thus set  $\epsilon = 5$  following Lanteri (2018) and  $\sigma^N = 0.5$ , thereby treating new and old capital symmetrically in production.<sup>22</sup> We further set the depreciation parameters  $\delta^N = \delta^O = 0.2$  so that the effective capital depreciation rate, accounting for the transition probability from new to old capital, and the equilibrium price of old capital, is approximately 10%. With these parameter values, the average age of new (old) capital is approximately equal to 4 (9) years.

The cost of equity issuance is a power function,  $\phi(-d) = \phi_0(-d)^{\phi_1}$  for  $d < 0$  and  $\phi(-d) = 0$  otherwise. A high value of  $\phi_1$  facilitates the computation of the constrained-efficient allocation, especially in the case in which the planner can only distort new investment; thus, we set  $\phi_1 = 5$ . We then set  $\phi_0 = 0.1$ , which implies marginal costs of equity in the range of the relevant empirical estimates—for example, Hennessy and Whited (2007) and Catherine, Chaney, Huang, Sraer, and Thesmar (2020). On average, firms in the model face a marginal cost of equity approximately equal to 6% of the issuance (16% conditional on firms that pay negative dividends in equilibrium). We set  $\theta = 0.5$ , implying that firms can borrow up to half of the resale value of their capital. This baseline value is close to

---

<sup>21</sup>With a production function  $y = k^{\alpha_k} n^{\alpha_n}$ , where  $n$  is labor, assuming time to build in capital and flexible labor choice, the effective elasticity of output with respect to capital that is relevant for investment is  $\alpha \equiv \frac{\alpha_k}{1-\alpha_n}$ . Common values in the investment literature are  $\alpha_k \approx 0.25$  and  $\alpha_n \approx 0.6$ , which support our choice of parameter value.

<sup>22</sup>Edgerton (2011) estimates the elasticity of substitution between new and old capital for several industries and finds values in the range between 1 and 10.

the estimates by Li, Whited, and Wu (2016). Moreover, we report results associated with  $\theta = 0$  and  $\theta = 0.75$  in Table A1 in the Appendix.<sup>23</sup>

The idiosyncratic productivity shock follows an AR(1) process in logs with persistence parameter  $\chi_s$  and standard deviation of innovations  $\sigma_s$ . We set  $\chi_s = 0.7$  and  $\sigma_s = 0.12$ , consistent with typical estimates in the literature on investment and reallocation with firm-level productivity shocks (Khan and Thomas, 2013, and Lanteri, 2018). We then discretize this process with a two-state Markov chain using the method of Rouwenhorst (1995). Given this process for the shocks, the standard deviation of firm-level investment rates in competitive equilibrium is equal to 0.29, close to empirical estimates (Cooper and Haltiwanger, 2006). We set  $\rho = 0.1$ , which approximately matches the average entry (and exit) rate for U.S. firms (Decker, Haltiwanger, Jarmin, and Miranda, 2014).

Newborn firms receive an initial net worth  $w_0 = 5$ , which corresponds to approximately 10% of the unconstrained-optimal capital level for high-productivity firms. Under this calibration, our model is broadly consistent with the evidence on the empirical relationship between firm age and capital age reported by Ma, Murfin, and Pratt (2020). They focus on equipment and find that age-0 firms buy machines that are on average 5.5 years old, whereas age-10 firms tend to buy capital that is on average 4 years old. In our model, which encompasses a broader notion of capital (including structures), the corresponding figures are 7.5 and 6.4 years.<sup>24</sup> Also consistent with their empirical findings, the slope of capital age with respect to firm age is steeper for younger firms, which are more financially constrained and thus purchase a larger share of old capital goods in our model.

## 5.2 Quantitative Results

Given our calibration, the stationary competitive-equilibrium price of old capital equals 0.553, whereas the first-best price of old capital equals 0.547. Equilibrium down payments and user costs (from the perspective of unconstrained firms) are

$$\wp_N \equiv 1 - \beta\theta(1 - \delta^N(1 - q)) = 0.563 > \wp_O \equiv q [1 - \beta\theta(1 - \delta^O)] = 0.340$$

---

<sup>23</sup>When solving the model for  $\theta = 1$ , we find that the competitive equilibrium is quantitatively close to the first-best allocation, as only newborn, high-productivity firms are financially constrained.

<sup>24</sup>Our quantitative model features a clear distinction between new and old capital, but does not necessarily distinguish between capital goods of different ages, given the partial depreciation structure with rates  $\delta^N$  and  $\delta^O$ . Thus, to compute firm-level capital age in the model, we first compute the *average* age of new capital and the *average* age of old capital, which are  $\frac{1-\delta^N}{\delta^N}$  and  $\frac{1-\delta^N}{\delta^N} + \frac{1}{\delta^O}$ , respectively. Specifically, the average age of new capital is 4 years and the average age of old capital is 9 years in our calibration. Next, we use the optimal portfolio weights on new and old capital for each firm to compute the average capital age for each firm, thereby assuming that the distribution of capital age within new capital and within old capital is homogeneous across firms.

Table 1: PARAMETER VALUES – CALIBRATION

		Parameter	Value
Preferences	Discount rate	$\beta$	0.96
Life cycle	Initial net worth	$w_0$	5
	Death probability	$\rho$	0.1
Technology	Curvature of production function	$\alpha$	0.6
	CES elasticity of substitution	$\epsilon$	5
	CES new capital share	$\sigma^N$	0.5
	Depreciation of new capital	$\delta^N$	0.2
	Depreciation of old capital	$\delta^O$	0.2
	Scrap value	$\underline{q}$	0.1
	Productivity persistence	$\chi_s$	0.7
	Productivity st. dev. of innovations	$\sigma_s$	0.12
Financial constraints	Collateralizability	$\theta$	0.5
	Cost of raising equity parameters	$\phi_0$	0.1
		$\phi_1$	5

and

$$u_N \equiv 1 - \beta(1 - \delta^N(1 - q)) = 0.126 < u_O \equiv q [1 - \beta(1 - \delta^O)] = 0.128,$$

respectively.

Figure 3 illustrates the key firm decision rules in the stationary competitive equilibrium (solid) and under the constrained efficient allocation (dashed). We start by discussing the policy functions in competitive equilibrium. Old capital accounts for a larger fraction of the capital operated by firms with lower net worth. As firms grow, they increase the share of new investment goods in their capital bundle. Furthermore, for a given level of net worth, firms with higher productivity are more financially constrained, as indicated by a higher marginal equity issuance cost, and thus choose a higher fraction of old capital goods. Thus, on average, the market for old capital reallocates assets from firms with high net worth and lower productivity to firms with low net worth and high productivity.

We now discuss the constrained-efficient allocation, when the planner chooses both new and old capital. We find that the planner optimally drives the price of old capital down to the scrappage value, thereby fostering capital reallocation toward financially constrained firms, which increase substantially their purchases of old capital and thus their overall productive capacity. The marginal value of net worth of the most constrained firms induced by this allocation is significantly lower than in the competitive equilibrium.

Figure 3: Stationary equilibrium and constrained efficient allocation. Top left: new capital  $k^N$ ; top right: old capital  $k^O$ ; bottom left: capital bundle  $k$ ; bottom right: marginal value of net worth  $\xi$ . The  $x$ -axes report net worth  $w$ . Solid lines denote the competitive-equilibrium allocation, dashed lines the constrained-efficient allocation. Thick lines denote the high productivity realization, thin lines the low realization.

We also compute the tax rates on new and old capital that implement the constrained-efficient allocation as a competitive equilibrium with taxes, rebated to each firm in a lump-sum fashion.<sup>25</sup> On average, the subsidy on new capital equals 8.6% and the tax on old capital equals 103.8%. Consistent with the intuition developed in our analytical results in Section 3.5, a large tax on old capital reflects the fact that the planner achieves a significant reduction of the price of old capital from its competitive-equilibrium value, which exceeds the first-best value, to the lower bound, the scrappage value  $\underline{q}$ .<sup>26</sup>

The large distortion on old capital motivates us to study a case in which only new-

<sup>25</sup>We illustrate these tax rates in Online Appendix OA.7.

<sup>26</sup>Accordingly, in Section 6.3 we analyze the sensitivity with respect to the scrappage value  $\underline{q}$  and find that optimal taxes on old capital are sensitive to this parameter. Specifically, a larger price reduction requires higher taxes on old capital to offset the effect of a low price on firms' optimal production scale.

capital taxes—rebated with lump-sum transfers to each firm—are available. We find that the restriction on the instrument set has a significant impact on the optimal allocation. The planner still instructs firms to increase their new investment, thereby decreasing the equilibrium price of old capital. The absence of taxes on old capital, however, implies that a reduction in the price of old capital induces unconstrained firms to also demand old capital and increase their size. Thus, this price reduction is significantly more muted than in the case in which the planner can also tax old capital. For the same reason, the optimal subsidy on new capital is smaller than in the previous case, and equals approximately 0.6%.

Next, we use our quantitative model to measure the pecuniary externalities in the stationary competitive equilibrium. Consistent with our analytical results, we find that the distributive externality dominates the collateral externality. Specifically, in the aggregate, we find that the distributive externality is approximately 2.3 times as large as the collateral externality.

In Figure 4, we explore the heterogeneous effects of the pecuniary externalities through the price of old capital, by displaying the cross section of distributive externalities (left panel) and collateral externalities (right panel) as functions of firms’ state variables. The distributive externality is defined as the marginal effect on firm value of *decreasing* the price of old capital due to a change in the value of old capital traded. This externality is largest for firms with low net worth and high productivity, because they are net buyers of old capital. As firms’ net worth increases, they eventually become net sellers of old capital, and the distributive externality accordingly becomes negative. The collateral externality is defined as the marginal effect on firm value of *increasing* the (future) price of collateral. This externality is also highest for the most financially constrained firms and goes to zero as firms become unconstrained. However, the figure confirms that overall the distributive externality is significantly larger and thus a reduction in the price of old capital is desirable.

In Table 2, we compare the key long-run aggregate outcomes under four alternative allocations: first best; competitive equilibrium; constrained efficiency when the planner chooses both types of capital; constrained efficiency when the planner chooses only new capital. Competitive-equilibrium and constrained-efficient allocations and prices are expressed as fractions of the corresponding first-best value, which we report in parenthesis in the first column. We find that financial frictions induce an aggregate output loss of approximately 10%, and an aggregate consumption loss of approximately 7%, relative to first best.<sup>27</sup> Notice that aggregate consumption is the relevant measure of welfare, under our assumption of linear utility. When the planner chooses both new and old capital, the constrained-efficient allocation increases output by 8% and consumption by 5% relative

---

<sup>27</sup>For comparison, Catherine, Chaney, Huang, Sraer, and Thesmar (2020) estimate the aggregate output cost of collateral constraints (and costly equity issuance) for US firms to be approximately 7%.

Figure 4: Pecuniary externalities in stationary equilibrium. Left panel: distributive externality; right panel: collateral externality. The  $x$ -axes report net worth  $w$ . Thick red lines denote the high productivity realization, thin blue lines the low realization. The distributive (collateral) externality is defined as the marginal effect on firm value of a decrease (increase) in the price of old capital. Using recursive notation, for a firm with state variables  $(w, s)$ , the distributive externality equals  $k^O(w, s)(1 + \phi_d(w, s)) - [\delta^N k^N(w, s) + (1 - \delta^O)k^O(w, s)] (1 + (1 - \rho)\mathbb{E}\phi_d(w', s'))$ , whereas the collateral externality equals  $\theta\lambda(w, s) [\delta^N k^N(w, s) + (1 - \delta^O)k^O(w, s)]$ .

to the competitive equilibrium. However, when the planner can only choose new capital, the gains are significantly smaller. In this case, aggregate output increases by slightly more than 2% and aggregate consumption by approximately 1% relative to competitive equilibrium.

## 6 Additional Analyses and Robustness

This section provides additional analyses of our quantitative model, by considering the transition dynamics, assessing the gains from the reallocation of old capital to more constrained firms, and evaluating the sensitivity of our quantitative results to key parameters.

### 6.1 Transition Dynamics

Our analysis has focused on stationary equilibria. We now perform an analysis of the transition dynamics associated with the implementation of subsidies on new investment. To make this analysis tractable, we consider the undistorted competitive equilibrium as the initial condition and assume that, unexpectedly, all firms face a common, time-invariant tax

Table 2: QUANTITATIVE RESULTS

Output, investment, consumption, and the price of used capital for the competitive equilibrium, the constrained efficient allocation, and the constrained efficient allocation without taxes on old capital are expressed as fractions of the corresponding first-best value, reported in parenthesis in the first column.

Variable	First Best	Comp. Eqm.	Constr. Eff.	Constr. Eff. ( $\tau^O = 0$ )
Output	(9.910)	0.899	0.973	0.921
Investment	(4.497)	0.857	0.962	0.893
Consumption	(5.413)	0.933	0.983	0.943
Price $q$	(0.547)	1.010	0.184	0.987
Average tax $\tau^N$	0	0	-8.6%	-0.6%
Average tax $\tau^O$	0	0	103.8%	n.a.

rate  $\tau^N$ . We consider a grid of values for  $\tau^N$ . For each value, we compute the associated final stationary equilibrium, as well as the transition dynamics keeping track of the distribution of firms and clearing the market for old capital in each period. We then find the level of  $\tau^N$  that maximizes household utility starting from the undistorted competitive equilibrium (that is, the present discounted value of aggregate consumption). Consistent with the key results of the paper, we find that the optimal tax rate on new capital is negative—that is, it is a subsidy on new capital—and approximately equal to -0.3%. We display these results in Online Appendix [OA.7](#).

## 6.2 Benchmarking the Gains From Reallocation

We have quantified the efficiency gains associated with optimal policy, and compared them to the undistorted competitive equilibrium. In order to provide further perspective on the size of these gains, we now compare our competitive equilibrium to a restricted allocation, in which all firms need to purchase new and old capital goods in the same fixed proportion. This analysis allows us to quantify the gains from reallocating old capital when firms face financial frictions. Specifically, we solve the firm optimization problem adding the constraint  $k_t^N(s^a)/k_t^O(s^a) = \delta^O/\delta^N$ , which is the aggregate ratio of new to old capital in steady state.<sup>28</sup> We find that removing the restriction induces aggregate welfare gains equal to approximately 0.4 percentage points of permanent consumption. We also find that the size of this gain is somewhat sensitive to the elasticity of substitution between new and

<sup>28</sup>Given this constraint, the market-clearing price is indeterminate. For comparison, we select the equilibrium associated with the same price of used capital as in the unrestricted competitive equilibrium.

old capital. Intuitively, the higher this elasticity, the more efficient it is for financially constrained firms to increase the share of old capital in their investment. For instance, the welfare gain from removing the restriction of constant investment shares increases to 0.8 percentage points of permanent consumption when we set  $\epsilon = 10$ . Thus, overall, we find that the gains from reallocating old capital in competitive equilibrium are comparable in size to the gains of going from competitive equilibrium to the optimal investment subsidy when the planner cannot distort purchases of old capital, but significantly smaller than the gains we obtain when the planner can choose both new and old capital.

### 6.3 Sensitivity

We now briefly discuss the sensitivity of our quantitative results with respect to changes in three parameters: the degree of collateralizability  $\theta$  (equal to 0.5 in the baseline calibration); the elasticity of substitution between new and old capital  $\epsilon$  (equal to 5 in the baseline calibration); and the scrap value  $\underline{q}$  (equal to 0.1 in the baseline calibration). We report all results related to this analysis in Table A1 in the Appendix.

We solve the model for  $\theta = 0$  (no borrowing) and  $\theta = 0.75$ . With  $\theta = 0$ , financial frictions induce substantially larger losses than in our baseline calibration. For instance, competitive-equilibrium output is approximately 20% lower than in the first-best allocation. Moreover, the only pecuniary externality is the distributive externality, contributing to larger gains from the optimal policy of subsidizing investment and reducing the price of old capital. With  $\theta = 0.75$ , the effects of financial frictions are smaller (competitive-equilibrium output is approximately 5% smaller than under first best), and, accordingly, so are the gains from optimal policy. The distributive externality is 27% larger than the collateral externality in competitive equilibrium. We find, however, that optimal tax rates on new and old capital are quite similar across all values of  $\theta$  we consider.

Next, we consider different values for  $\epsilon$ , namely  $\epsilon = 1$  and  $\epsilon = 10$ . We find that our results are quite robust with respect to these changes. The higher the elasticity of substitution, however, the more effective the planner is in allowing constrained firms to produce at a larger scale by using a larger share of old capital, consistent with our theoretical result that first-best welfare can be achieved with perfect substitutability (Section 3.5).

Finally, we consider a lower and a higher scrap value ( $\underline{q} = 0.05$  and  $\underline{q} = 0.2$ ) relative to our baseline value ( $\underline{q} = 0.1$ ), to investigate whether this lower bound for the price of old capital, which is a binding constraint for the planner, is important for our results. We find that optimal allocations are similar, irrespective of this change, and, intuitively, welfare gains are larger, the lower the scrap value. We also find that the optimal tax on old capital that supports the constrained-efficient allocation is highly sensitive with respect to this

parameter, ranging from approximately 40% when  $\underline{q} = 0.2$  to approximately 230% when  $\underline{q} = 0.05$ .

## 7 Conclusion

We analyze the constrained-efficient allocation in an equilibrium model of investment and capital reallocation both theoretically and quantitatively. Financial frictions induce pecuniary externalities in the secondary market for capital. Because financially constrained firms tend to be net buyers of old capital, and unconstrained firms tend to sell old capital and replace it with new capital, the competitive-equilibrium price of old capital is inefficiently high. This distributive externality dominates the collateral externality, which would call for increasing the resale price of capital instead, and which is the focus of much of the existing quantitative literature using models with a representative firm. A planner can induce a more efficient allocation by subsidizing new capital, thereby increasing the future supply of old capital and thus alleviating the effects of financial constraints for constrained firms in the future.

Subsidies on new investment are a widely-used policy tool.<sup>29</sup> Despite their popularity, to the best of our knowledge there is scarce theoretical foundation for these policies. Our analysis highlights that new investment induces a positive externality by fostering capital reallocation, thus providing a rationale for investment subsidies. We also show the efficiency gains associated with investment subsidies are tightly linked to equilibrium prices and policy interventions in secondary markets, thus providing a new perspective and guidance on the optimal design of investment incentives.

---

<sup>29</sup>For instance, in the US, bonus depreciation is a federal budget provision that historically subsidized investment in new equipment. Since 2018, this provision has been extended to include purchases of used capital goods at least until 2023. According to the Joint Committee on Taxation, the estimated cost of this scheme was approximately 63 billion dollars in 2019.

# APPENDIX

This appendix provides additional details and proofs for the stylized model of Section 3.

## A.1 Lagrangian for Constrained-Efficient Allocation

In this section, we explicitly formulate the Lagrangian of the problem discussed in Section 3.4. The planner chooses sequences of functions  $\{d_{0t}(w), d_{1,t+1}(w), k_{t+1}^N(w), k_{t+1}^O(w), b_{t+1}(w)\}_{t=0}^{\infty}$  and a sequence of prices  $\{q_t\}_{t=0}^{\infty}$ , given an initial condition  $(k_0^N(w), k_0^O(w), b_0(w))$ , to maximize the present discounted value of aggregate dividends – or equivalently, aggregate consumption – subject to the sequence of firms’ budget constraints when young and old (with multipliers  $\mu_{0t}(w)$  and  $\mu_{1t+1}(w)$ , respectively), collateral constraints (with multiplier  $\lambda_t(w)$ ), non-negativity constraints on new and old capital (with multipliers  $\underline{\nu}_t^N(w)$  and  $\underline{\nu}_t^O(w)$ , respectively), and market-clearing conditions for old capital (with multiplier  $\eta_t$ ). We now state the Lagrangian of this problem, dropping the dependence of allocation and distribution on net worth  $w$  to simplify notation:

$$\begin{aligned} \mathcal{L} \equiv & \sum_{t=0}^{\infty} \beta^t \left\{ \int (d_{0t} - \phi(-d_{0t}) + d_{1t}) d\pi - \int \mu_{0t} (d_{0t} - w - b_t + k_t^N + q_t k_t^O) d\pi \right. \\ & - \int \mu_{1t} (d_{1t} - f(k_{t-1}^N + k_{t-1}^O) - q_t k_{t-1}^N + \beta^{-1} b_{t-1}) d\pi + \int \lambda_t (\beta \theta q_{t+1} k_t^N - b_t) d\pi \\ & \left. + \int \underline{\nu}_t^N k_t^N d\pi + \int \underline{\nu}_t^O k_t^O d\pi - \eta_t \left( \int k_t^O d\pi - \int k_{t-1}^N d\pi \right) \right\}. \end{aligned}$$

## A.2 Firm Life Cycle and Long-Lived Capital

In this section, we discuss the model with a stochastic firm life cycle and long-lived capital from Section 3.8 in more detail and we prove Proposition 5.

*Competitive Equilibrium with Financial Frictions.* The expected present discounted value of dividends, net of equity issuance costs, of a firm born at time  $t$  is

$$\sum_{a=0}^{\infty} \beta^a \gamma_a [(d_{a,t+a} - \phi(-d_{a,t+a}))] + \sum_{a=1}^{\infty} \beta^a \gamma_{a-1} \rho w_{a,t+a}$$

where  $d_{at}$  are dividends of continuing firms of age  $a$  at time  $t$  and  $w_{at}$  is net worth. We leave implicit the dependence of allocations on initial firm net worth  $w_0$  to simplify notation.

The dividend of a continuing firm satisfies the following budget constraint:

$$d_{at} = w_{at} + b_{at} - k_{at}^N - q_t k_{at}^O$$

where  $k_{at}^N$  and  $k_{at}^O$  are investments in new and old capital, respectively,  $q_t$  is the price of old capital, and  $b_{at}$  is debt. Firm net worth evolves as follows. For  $a > 0$ , we have

$$w_{at} = f(k_{a-1,t-1}) + (1 - \delta^N(1 - q_t))k_{a-1,t-1}^N + q_t(1 - \delta^O)k_{a-1,t-1}^O - \beta^{-1}b_{a-1,t-1}$$

where  $k_{a-1,t-1} = k_{a-1,t-1}^N + k_{a-1,t-1}^O$  and  $\beta^{-1}$  is the gross interest rate.

Firms face a collateral constraint, which states that debt cannot exceed a fraction  $\theta$  of the resale value of new and old capital:

$$\theta [(1 - \delta^N(1 - q_{t+1}))k_{at}^N + q_{t+1}(1 - \delta^O)k_{at}^O] \geq \beta^{-1}b_{at}.$$

Denote the multiplier on the collateral constraint by  $\beta^{t+1}\lambda_{at}$  and the marginal equity issuance cost by  $\phi_{d,at}$ . The firm's optimality conditions for new capital, old capital, and debt, are

$$\begin{aligned} 1 + \phi_{d,at} &= \beta [f_k(k_{at}) + (1 - \delta^N(1 - q_{t+1}))] (1 + (1 - \rho)\phi_{d,a+1,t+1}) \\ &\quad + \beta\theta\lambda_{at}(1 - \delta^N(1 - q_{t+1})) \\ q_t(1 + \phi_{d,at}) &= \beta [f_k(k_{at}) + (1 - \delta^O)q_{t+1}] (1 + (1 - \rho)\phi_{d,a+1,t+1}) \\ &\quad + \beta\theta\lambda_{at}(1 - \delta^O)q_{t+1} \\ \phi_{d,at} &= (1 - \rho)\phi_{d,a+1,t+1} + \lambda_{at}. \end{aligned}$$

The market-clearing condition for old capital is

$$\int \sum_{a=0}^{\infty} \gamma_a [\delta^N k_{a,t-1}^N + (1 - \delta^O)k_{a,t-1}^O] d\pi_0(w_0) = \int \sum_{a=0}^{\infty} \gamma_a k_{at}^O d\pi_0(w_0).$$

We define a stationary competitive equilibrium writing the firm problem and the market clearing condition recursively. A *stationary competitive equilibrium* is a set of policy functions mapping net worth to an allocation, that is, dividends, investment, and borrowing choices for continuing firms,  $\{d(w), k^N(w), k^O(w), b(w)\}$ , a stationary distribution of net worth  $\pi(w)$ , and a price of old capital  $q$ , such that firms maximize the present discounted value of dividends net of equity issuance cost,  $\forall w$ , the stationary distribution is consistent with firms' policy functions, and the market for old capital clears, that is,  $\int k^N(w)d\pi(w) = \int k^O(w)d\pi(w)$ . Notice that the stationary distribution of net worth  $\pi$  is an equilibrium object, whereas the distribution of net worth of new firms  $\pi_0$  is taken as exogenous.

With long-lived capital, we define the down payment per unit of new and old capital

as  $\wp_N \equiv 1 - \beta\theta(1 - \delta^N(1 - q))$  and  $\wp_O \equiv q(1 - \beta\theta(1 - \delta^O))$ , respectively, and the user cost of new and old capital to an unconstrained firm as  $u_N \equiv 1 - \beta(1 - \delta^N(1 - q))$  and  $u_O \equiv q(1 - \beta(1 - \delta^O))$ , respectively. Analogously to (15) and (16) we define the user cost of new and old capital to a firm with net worth  $w$  as

$$u_N(w) \equiv u_N + \phi_d \wp_N = 1 - \beta(1 - \delta^N(1 - q)) + \phi_d(1 - \beta\theta(1 - \delta^N(1 - q)))$$

and

$$u_O(w) \equiv u_O + \phi_d \wp_O = q(1 - \beta(1 - \delta^O)) + \phi_d(1 - \beta\theta(1 - \delta^O)),$$

respectively. The investment Euler equations for new and old capital are

$$1 = \beta \left( \frac{1 + (1 - \rho)\phi'_d}{1 + \phi_d} \right) \frac{f_k(k) + \beta(1 - \theta)(1 - \delta^N(1 - q))}{\wp_N} + \frac{\underline{\nu}_N/(1 + \phi_d)}{\wp_N} \quad (\text{A1})$$

$$1 = \beta \left( \frac{1 + (1 - \rho)\phi'_d}{1 + \phi_d} \right) \frac{f_k(k) + \beta(1 - \theta)(1 - \delta^O)}{\wp_O} + \frac{\underline{\nu}_O/(1 + \phi_d)}{\wp_O}. \quad (\text{A2})$$

Combining these two Euler equations we obtain

$$1 = \beta \left( \frac{1 + (1 - \rho)\phi'_d}{1 + \phi_d} \right) \frac{(1 - \theta)((1 - \delta^N(1 - q)) - q(1 - \delta^O))}{\wp_N - \wp_O} + \frac{(\underline{\nu}_N - \underline{\nu}_O)/(1 + \phi_d)}{\wp_N - \wp_O}. \quad (\text{A3})$$

To see that  $q < 1$  in a stationary equilibrium, suppose instead that  $q \geq 1$ ; then  $u_O > u_N$  and  $\wp_O > \wp_N$ , implying that old capital would be dominated. To see that  $\wp_N > \wp_O$  in a stationary equilibrium, suppose instead that  $\wp_N \leq \wp_O$ ; then (A3) would imply that  $\underline{\nu}_O > 0$ , that is, no firms would invest in old capital, a contradiction. Note that  $\wp_N > \wp_O$  is equivalent to

$$q < \frac{1 - \beta\theta(1 - \delta^N)}{1 + \beta\theta\delta^N - \beta\theta(1 - \delta^O)} < 1.$$

To see that  $u_N \leq u_O$  in a stationary equilibrium, note that otherwise  $u_N(w) > u_O(w)$  for all firms, so there would not be any new investment, which cannot be an equilibrium. Further,  $u_N \leq u_O$  is equivalent to

$$q \geq q^{FB} \equiv \frac{1 - \beta(1 - \delta^N)}{1 + \beta\delta^N - \beta(1 - \delta^O)},$$

that is, the price of old capital in competitive equilibrium must be weakly higher than the price of old capital in a frictionless economy.

Let  $R_O \equiv \frac{(1 - \theta)((1 - \delta^N(1 - q)) - q(1 - \delta^O))}{\wp_N - \wp_O}$ . Since  $q \geq q^{FB}$ ,  $R^O \geq \beta^{-1}$  (with equality if  $q = q^{FB}$ ). For firms that are indifferent between investing in new and old capital we can write (A3)

as

$$1 = \beta \left( \frac{1 + (1 - \rho)\phi'_d}{1 + \phi_d} \right) R_O.$$

For such firms, we can then write the investment Euler equation for new capital (A1) as

$$1 = R_O^{-1} \frac{f_k(k) + (1 - \theta)(1 - \delta^N(1 - q))}{\wp_N},$$

implying that such firms all invest the same amount  $\underline{k}$ . (If  $q = q^{FB}$ , then  $\underline{k} = k^{FB}$ .)

*Constrained Efficiency.* The planner maximizes the present discounted value of aggregate dividends net of equity issuance costs

$$\sum_{t=0}^{\infty} \beta^t \int \left[ \sum_{a=0}^{\infty} \gamma_a [(d_{at} - \phi(-d_{at}))] + \sum_{a=1}^{\infty} \gamma_{a-1} \rho w_{at} \right] d\pi_0(w_0) \quad (\text{A4})$$

subject to the transition for net worth, the collateral constraint and the market-clearing condition for old capital, with multiplier  $\eta_t$ .

The optimality condition for the price of old capital is

$$\int \sum_{a=0}^{\infty} \gamma_a k_{at}^O (1 + \phi_{d,at}) d\pi_0(w_0) = \int \sum_{a=0}^{\infty} \gamma_a [\delta^N k_{a,t-1}^N + (1 - \delta^O) k_{a,t-1}^O] (1 + (1 - \rho)\phi_{d,a+1,t} + \theta \lambda_{a,t-1}) d\pi_0(w_0). \quad (\text{A5})$$

The summation on the left-hand side of equation (A5) represents the marginal cost of increasing the price  $q_t$  for firms that purchase old capital. The summation on the right-hand side represents the marginal benefit of increasing net worth for firms that own old capital, as well as the marginal effect of  $q_t$  on the borrowing capacity of constrained firms at  $t - 1$ .

We now prove that in the stationary competitive equilibrium the distributive externality is larger than the collateral externality, that is,

$$\int \sum_{a=0}^{\infty} \gamma_a k_{at}^O (1 + \phi_{d,at}) d\pi_0(w_0) > \int \sum_{a=0}^{\infty} \gamma_a [\delta^N k_{a,t-1}^N + (1 - \delta^O) k_{a,t-1}^O] (1 + (1 - \rho)\phi_{d,a+1,t} + \theta \lambda_{a,t-1}) d\pi_0(w_0),$$

or, written recursively,

$$\int k^O(w)(1 + \phi_d(w))d\pi(w) > \int [\delta^N k^N(w) + (1 - \delta^O)k^O(w)] (1 + (1 - \rho)\phi_d(w') + \theta\lambda(w))d\pi(w)$$

where  $w'$  denotes future net worth associated with current net worth  $w$ . Simplifying using the market-clearing condition, we have

$$\int k^O(w)\phi_d(w)d\pi(w) > \int [\delta^N k^N(w) + (1 - \delta^O)k^O(w)] ((1 - \rho)\phi_d(w') + \theta\lambda(w))d\pi(w).$$

Using the first-order condition for debt to substitute out  $\lambda(w)$ , we obtain

$$\int k^O(w)\phi_d(w)d\pi(w) > \int [\delta^N k^N(w) + (1 - \delta^O)k^O(w)] (\theta\phi_d(w) + (1 - \theta)(1 - \rho)\phi_d(w'))d\pi(w). \quad (\text{A6})$$

Notice that  $\phi_d$  is weakly decreasing in net worth. Moreover,  $\phi_d(w) \geq \theta\phi_d(w) + (1 - \theta)(1 - \rho)\phi_d(w')$ . Hence, if inequality (A6) holds (weakly) for  $\theta = 1$ , it holds (strictly) for any  $\theta < 1$ . Accordingly, we now prove the following inequality:

$$\int k^O(w)\phi_d(w)d\pi(w) \geq \int [\delta^N k^N(w) + (1 - \delta^O)k^O(w)] \phi_d(w)d\pi(w),$$

which, rearranging, we can equivalently express as follows

$$\delta^O \int k^O(w)\phi_d(w)d\pi(w) \geq \delta^N \int k^N(w)\phi_d(w)d\pi(w). \quad (\text{A7})$$

As no firm invests in old capital above  $\bar{w}_O$ , market clearing implies:

$$\delta^O \int^{\bar{w}_O} k^O(w)d\pi(w) \geq \delta^N \int_{\underline{w}_N}^{\bar{w}} k^N(w)d\pi(w). \quad (\text{A8})$$

Furthermore, we can bound the two sides of (A7) as follows. Since  $\phi_d(w)$  is weakly decreasing in  $w$ ,

$$\int^{\underline{w}_N} k^O(w)\phi_d(w)d\pi(w) \geq \phi_d(\underline{w}_N) \int^{\underline{w}_N} k^O(w)d\pi(w). \quad (\text{A9})$$

In the region of indifference between new and old capital, we apply the following result:  $\mathbb{E}[k^O\phi_d] = \text{COV}(k^O, \phi_d) + \mathbb{E}[k^O]\mathbb{E}[\phi_d]$ . Since  $k^O$  and  $\phi_d$  are both decreasing in  $w$ , we have

$\text{COV}(k^O, \phi_d) \geq 0$ .<sup>30</sup> Thus,

$$\int_{\underline{w}_N}^{\bar{w}^O} k^O(w) \phi_d(w) d\pi(w) \geq \bar{\phi}_d \int_{\underline{w}_N}^{\bar{w}^O} k^O(w) d\pi(w) \quad (\text{A10})$$

where  $\bar{\phi}_d \equiv \int_{\underline{w}_N}^{\bar{w}^O} \phi_d(w) d\pi(w)$ . Since  $\phi_d(\underline{w}_N) \geq \bar{\phi}_d$ , we can combine (A9) and (A10) and get

$$\int_{\underline{w}_N}^{\bar{w}^O} k^O(w) \phi_d(w) d\pi(w) \geq \bar{\phi}_d \int_{\underline{w}_N}^{\bar{w}^O} k^O(w) d\pi(w). \quad (\text{A11})$$

Analogously, since  $k^N$  is increasing in  $w$ , we obtain

$$\int_{\underline{w}_N}^{\bar{w}} k^N(w) \phi_d(w) d\pi(w) \leq \bar{\phi}_d \int_{\underline{w}_N}^{\bar{w}} k^N(w) d\pi(w). \quad (\text{A12})$$

Notice that our characterization of the stationary equilibrium implies  $\int_{\bar{w}^O} k^O(w) \phi_d(w) d\pi(w) = \int_{\bar{w}} k^N(w) \phi_d(w) d\pi(w) = 0$ . Hence, combining (A8), (A11), and (A12), we get

$$\delta^O \int k^O(w) \phi_d(w) d\pi(w) \geq \delta^N \int k^N(w) \phi_d(w) d\pi(w),$$

which, given  $\theta < 1$ , proves Proposition 5.

---

<sup>30</sup>See Schmidt (2003) for a proof of this result.

Table A1: QUANTITATIVE RESULTS – SENSITIVITY ANALYSIS

This table provides the sensitivity analysis of the quantitative results with respect the collateralizability  $\theta$  (Panel A), elasticity of substitution  $\epsilon$  (Panel B), and scrap value  $\underline{q}$  (Panel C). Output, investment, consumption, and the price of used capital for the competitive equilibrium and constrained efficient allocation are expressed as fractions of the corresponding first-best value, reported in parenthesis the first column of Panel A.

# ONLINE APPENDIX – Not for Publication

## OA.1 Constrained-Efficient Allocation: No Taxes on Old Capital

In this section, we discuss the problem introduced at the end of Section 3.5. Relative to the problem described in Appendix A.1, we impose the following additional constraint for all firms:

$$q_t(1 + \phi_{d,t}) \geq \beta f_k(k_t),$$

which is equivalent to imposing that the planner cannot tax old capital in the implementation with taxes on new and old capital.

The Lagrangian of this problem is

$$\begin{aligned} \mathcal{L} \equiv & \sum_{t=0}^{\infty} \beta^t \left\{ \int (d_{0t} - \phi(-d_{0t}) + d_{1t}) d\pi - \int \gamma_{0t} (d_{0t} - w - b_t + k_t^N + q_t k_t^O) d\pi \right. \\ & - \int \gamma_{1t} (d_{1t} - f(k_{t-1}^N + k_{t-1}^O) - q_t k_{t-1}^N + \beta^{-1} b_{t-1}) d\pi + \int \lambda_t (\beta \theta q_{t+1} k_t^N - b_t) d\pi \\ & \left. + \int \psi_t (q_t(1 + \phi_{d,t}) - \beta f_k(k_t^N + k_t^O)) d\pi + \int \underline{\nu}_t^N k_t^N d\pi + \int \underline{\nu}_t^O k_t^O d\pi - \eta_t \left( \int k_t^O d\pi - \int k_{t-1}^N d\pi \right) \right\}. \end{aligned}$$

The first-order conditions with respect to new capital, old capital, and debt are

$$1 + \phi_{d,t} = \beta [f_k(k_t) + q_{t+1}] + \beta \theta \lambda_t q_{t+1} + \beta \eta_{t+1} + \psi_t [q_t \phi_{dd,t} - \beta f_{kk}(k_t)] + \underline{\nu}_t^N \quad (\text{OA1})$$

$$q_t(1 + \phi_{d,t}) = \beta f_k(k_t) - \eta_t + \psi_t [q_t^2 \phi_{dd,t} - \beta f_{kk}(k_t)] + \underline{\nu}_t^O \quad (\text{OA2})$$

$$1 + \phi_{d,t} = 1 + \lambda_t + \psi_t q_t \phi_{dd,t}, \quad (\text{OA3})$$

and the first-order condition with respect to the price of old capital is

$$\int k_t^O (1 + \phi_{d,t}) d\pi = \int k_{t-1}^N (1 + \theta \lambda_{t-1}) d\pi + \int \psi_t (1 + \phi_{d,t} + q_t \phi_{dd,t} k_t^O) d\pi. \quad (\text{OA4})$$

The complementary slackness condition is

$$\psi_t [q_t(1 + \phi_{d,t}) - \beta f_k(k_t)] = 0,$$

and thus for firms that buy a positive amount of old capital, (OA2) implies that

$$\psi_t = \frac{\eta_t}{q_t^2 \phi_{dd,t} - \beta f_{kk}(k_t)}.$$

Consider firms that purchase a strictly positive amount of new capital; for such firms,

equation (OA1) in stationary equilibrium is

$$1 + \phi_d = \beta [f_k(k) + q] + \beta\theta\lambda q + \beta\eta + \psi [q\phi_{dd} - \beta f_{kk}(k)].$$

Compare this optimality condition of the planner with the analogous competitive-equilibrium condition in the presence of taxes on new capital for such firms:

$$(1 + \phi_d)(1 + \tau^N) = \beta [f_k(k) + q] + \beta\theta\lambda q.$$

Because  $\eta \geq 0$  and  $\psi \geq 0$ , we have  $\tau^N \leq 0$ . We assume that the planner can also use a tax on debt to induce its desired value for the multiplier  $\lambda$  in competitive equilibrium, consistent with equation (OA3). With a tax on borrowing  $\tau^B$ , the first-order condition for debt is  $(1 + \phi_d)/(1 + \tau^B) = 1 + \lambda$ , which by comparing to (OA3) implies that  $\tau^B \geq 0$ .<sup>31</sup>

We solve for this allocation in our numerical example with parameter values as in the example in Figure 1 and display the policy functions in Figure OA1. We find that the average subsidy on new capital is approximately 1%. The price of old capital is approximately 2% lower than in competitive equilibrium: the planner is severely constrained in reducing the price of old capital, because a low price induces unconstrained firms to also buy old capital, given that these purchases cannot be taxed. This is reflected in the last term on the right-hand-side of equation (OA4), which must be positive, implying that the planner must tolerate a distributive externality that is larger than the collateral externality, and thus cannot achieve the first-best level of welfare.

## OA.2 Risk-Averse Entrepreneurs

In this section, we analyze the case from Section 3.6 in which each firm is owned by a risk-averse entrepreneur whose consumption at each date equals the dividend paid by the firm.

*Competitive Equilibrium with Financial Frictions.* Given their initial net worth  $w$  and the price of old capital  $q_t$ , entrepreneurs maximize their utility by choosing consumption  $c_{0t}$  and  $c_{1,t+1}$ , new and old capital  $k_t^N$  and  $k_t^O$ , and borrowing  $b_t$ , to solve<sup>32</sup>

$$\max_{\{c_{0t}, c_{1,t+1}, k_t^N, k_t^O, b_t\} \in \mathbb{R}_+^4 \times \mathbb{R}} u(c_{0t}) + \beta u(c_{1,t+1}) \quad (\text{OA5})$$

---

<sup>31</sup>Numerically, in our example this assumption is immaterial for the sign of  $\tau^N$ , and we obtain a similar subsidy if we impose the absence of taxes on debt.

<sup>32</sup>Because we now interpret dividends as consumption, we require that dividends are non-negative. We could alternatively allow for negative dividends, in which case this model becomes a generalization of our stylized model, which can be obtained as the special case  $u(d) \equiv d - \phi(d)$ .

Figure OA1: Stationary competitive equilibrium and constrained-efficient allocation (new-capital taxes only) – example. Top left: new capital  $k^N$ ; top right: old capital  $k^O$ ; bottom left: total capital  $k$ ; bottom right: marginal cost of equity issuance  $\phi_d$ . The  $x$ -axes report net worth  $w$ . Solid lines denote the competitive-equilibrium allocation, dashed lines the constrained-efficient allocation. See the caption of Figure 1 for the parameter values.

where  $u$  is the utility function, with  $u_c > 0$ ,  $u_{cc} < 0$ , and  $\lim_{c \rightarrow 0} u_c(c) = +\infty$ , subject to the budget constraints for the current and next period,

$$w_{0t} + b_t = c_{0t} + k_t^N + q_t k_t^O \quad (\text{OA6})$$

$$f(k_t^N + k_t^O) + q_{t+1} k_t^N = c_{1,t+1} + \beta^{-1} b_t, \quad (\text{OA7})$$

and the collateral constraint

$$\theta q_{t+1} k_t^N \geq \beta^{-1} b_t. \quad (\text{OA8})$$

Denote the multipliers on the budget constraints by  $\mu_{0t}$  and  $\beta\mu_{1,t+1}$ , on the collateral constraint by  $\beta\lambda_t$ , and on non-negativity constraint for new and old capital by  $\underline{\nu}_t^N$  and  $\underline{\nu}_t^O$ , respectively. The optimal demand for new capital, old capital, and borrowing, as functions

of initial net worth  $w$ , satisfy the following first-order conditions

$$u_c(c_{0t}) = \beta u_c(c_{1,t+1}) [f_k(k_t) + q_{t+1}] + \beta \theta \lambda_t q_{t+1} + \underline{v}_t^N \quad (\text{OA9})$$

$$q_t u_c(c_{0t}) = \beta u_c(c_{1,t+1}) f_k(k_t) + \underline{v}_t^O \quad (\text{OA10})$$

$$u_c(c_{0t}) = u_c(c_{1,t+1}) + \lambda_t, \quad (\text{OA11})$$

where  $k_t = k_t^N + k_t^O$ . Moreover, the firm's marginal value of net worth at date  $t$  is  $\mu_{0,t} = u_c(c_{0t})$ .

A *stationary competitive equilibrium* is a set of policy functions mapping initial net worth to an allocation  $\{c_0(w), c_1(w), k^N(w), k^O(w), b(w)\}$ , that is, consumption, investment, and debt choices, and a price of old capital  $q$ , such that entrepreneurs maximize their utility,  $\forall w \in \mathcal{W}$ , and the market for old capital clears, that is,  $\int k^N(w) d\pi(w) = \int k^O(w) d\pi(w)$ .

In a stationary equilibrium, the first-order conditions for new and old capital (OA9) and (OA10) can be written as investment Euler equations

$$1 \geq \beta \frac{u_c(c_1)}{u_c(c_0)} \frac{[f_k(k) + (1 - \theta)q]}{\varphi_N} \quad (\text{OA12})$$

$$1 \geq \beta \frac{u_c(c_1)}{u_c(c_0)} \frac{f_k(k)}{q}, \quad (\text{OA13})$$

with equality if  $k^N > 0$  and  $k^O > 0$ , respectively, where we use the same definition of the down payments as in Section 3.

Using (OA11), we can rewrite (OA12) and (OA13) as

$$\begin{aligned} u_N(w) \equiv u_N + \frac{\lambda}{u_c(c_1)} \varphi_N &= 1 - \beta q + \frac{\lambda}{u_c(c_1)} (1 - \beta \theta q) \geq \beta f_k(k) \\ u_O(w) \equiv u_O + \frac{\lambda}{u_c(c_1)} \varphi_O &= q + \frac{\lambda}{u_c(c_1)} q \geq \beta f_k(k), \end{aligned}$$

where we use the same definitions of the user cost as in Section 3.

Combining (OA12) and (OA13) we moreover have

$$1 = \beta \frac{u_c(c_1)}{u_c(c_0)} \frac{(1 - \theta)q}{\varphi_N - \varphi_O} + \frac{(\underline{v}_N - \underline{v}_O)/u_c(c_0)}{\varphi_N - \varphi_O}. \quad (\text{OA14})$$

Equation (OA14) implies  $\varphi_N > \varphi_O$ . Thus, in equilibrium,  $u_N \leq u_O$ . Consider first entrepreneurs for which  $\lambda = 0$ . They invest  $\bar{k}$  which solves  $1 = \beta \frac{f_k(\bar{k}) + (1 - \theta)q}{\varphi_N}$ . Moreover  $k^N = \bar{k}$  and  $k^O = 0$  if  $q > q^{FB}$ . Entrepreneurs with  $\lambda = 0$  have net worth  $w \geq \bar{w}$ , where  $\bar{w}$  solves  $\bar{w} - \varphi_N \bar{k} = f(\bar{k}) + (1 - \theta)q \bar{k}$ .

Entrepreneurs with sufficiently low  $w$  strictly prefer old capital, because as  $w \rightarrow 0$ ,  $f_k(k) \rightarrow +\infty$  and therefore  $\frac{u_c(c_1)}{u_c(c_0)} \rightarrow 0$ , and thus equation (OA14) implies  $\underline{\nu}_N > 0$ . Hence, for sufficiently low  $w$ ,  $k^N = 0$  and  $k^O > 0$ . Moreover,  $k^O$  is strictly increasing in  $w$ . To see this, consider  $w_+ > w$  and assume  $k_+^O \leq k^O$ . Then,  $c_{1,+} = f(k_+^O) \leq f(k^O) = c_1$  and  $f_k(k_+^O) \geq f_k(k^O)$ , whereas  $\frac{u_c(c_{1,+})}{u_c(c_{0,+})} > \frac{u_c(c_{1,+})}{u_c(c_0)} \geq \frac{u_c(c_1)}{u_c(c_0)}$ , which contradicts equation (OA13).

For  $w$  sufficiently close to  $\bar{w}$  and  $w < \bar{w}$ ,  $k^N > 0$  and  $k^O = 0$ . Hence (OA12) holds with equality. Moreover,  $k^N$  is strictly increasing in  $w$ . To see this, consider  $w_+ > w$  and assume  $k_+^N \leq k^N$ . Then,  $f_k(k_+^N) \geq f_k(k^N)$ , whereas  $c_{1,+} = f(k_+^N) + q(1 - \theta)k_+^N \leq f(k^N) + q(1 - \theta)k^N = c_1$  and hence  $\frac{u_c(c_{1,+})}{u_c(c_{0,+})} > \frac{u_c(c_{1,+})}{u_c(c_0)} \geq \frac{u_c(c_1)}{u_c(c_0)}$ , which contradicts equation (OA12).

Consider now entrepreneurs for which  $\underline{\nu}_N = \underline{\nu}_O = 0$ . Then,  $1 = \beta \frac{u_c(c_1)}{u_c(c_0)} R_O$ , where  $R_O = \frac{(1-\theta)q}{\varphi_N - \varphi_O}$ . Since  $c_0$  is strictly increasing in  $w$ ,  $c_1$  is strictly increasing in  $w$ . Moreover  $1 = R_O^{-1} \frac{[f_k(k) + (1-\theta)q]}{\varphi_N} = R_O^{-1} \frac{f_k(k)}{q}$ . Hence,  $k = \underline{k} \leq \bar{k}$ . Since  $c_1 = f(\underline{k}) + (1 - \theta)qk^N$ ,  $k^N$  is strictly increasing and  $k^O = \underline{k} - k^N$  is strictly decreasing in  $w$ .

Entrepreneurs who are indifferent between new and old capital have net worth  $\underline{w}_N \leq w \leq \bar{w}_O \leq \bar{w}$  and these thresholds are implicitly characterized as follows:  $c_0(\underline{w}_N) = \underline{w}_N - q\underline{k}$ ,  $c_1(\underline{w}_N) = f(\underline{k})$ ,  $1 = \beta R_O \frac{u_c(c_1(\underline{w}_N))}{u_c(c_0(\underline{w}_N))}$ ;  $c_0(\bar{w}_O) = \underline{w}_N - \varphi_N \underline{k}$ ,  $c_1(\bar{w}_O) = f(\underline{k}) + (1 - \theta)q\underline{k}$ ,  $1 = \beta R_O \frac{u_c(c_1(\bar{w}_O))}{u_c(c_0(\bar{w}_O))}$ .

*Constrained Efficiency.* Given an initial distribution of new and old capital,  $k_{-1}^N(w)$  and  $k_{-1}^O(w)$ , a utilitarian planner maximizes the total present discounted value of utility

$$\int \left[ u(c_{10}(w)) + \sum_{t=0}^{\infty} \beta^t (u(c_{0t}(w)) + \beta u(c_{1,t+1}(w))) \right] d\pi(w),$$

subject to the budget constraints (OA6) and (OA7) with multipliers  $\beta^t \mu_{0,t}$  and  $\beta^{t+1} \mu_{1,t+1}$ , the collateral constraint (OA8) with multiplier  $\beta^{t+1} \lambda_t$ , the non-negativity constraints on new and old capital with multipliers  $\beta^t \underline{\nu}_t^N$  and  $\beta^t \underline{\nu}_t^O$ , and the market clearing condition for old capital (3) with multiplier  $\beta^t \eta_t$ .

The first-order condition with respect to the price of old capital  $q_t$  for  $t = 1, 2, \dots$  is

$$\int k_t^O(w) u_c(c_{0t}(w)) d\pi(w) = \int k_{t-1}^N(w) [u_c(c_{1t}(w)) + \theta \lambda_{t-1}(w)] d\pi(w).$$

Thus, in the stationary constrained-efficient allocation, we have

$$\int k^O(w) u_c(c_0(w)) d\pi(w) = \int k^N(w) [u_c(c_1(w)) + \theta \lambda(w)] d\pi(w).$$

We now show that, in stationary competitive equilibrium, the distributive externality

is larger than the collateral externality, that is,

$$\int k^O(w)u_c(c_0(w))d\pi(w) > \int k^N(w)[u_c(c_1(w)) + \theta\lambda(w)]d\pi(w).$$

To do so, it is sufficient to prove that

$$\int k^O(w)u_c(c_0(w))d\pi(w) > \int k^N(w)u_c(c_0(w))d\pi(w), \quad (\text{OA15})$$

because  $u_c(c_0(w)) = u_c(c_1(w)) + \lambda(w) \geq u_c(c_1(w)) + \theta\lambda(w)$ .

We can bound the two sides of (OA15) as follows. Let  $\bar{u}_c \equiv \int_{\underline{w}_N}^{\bar{w}_O} u_c(c_0(w))d\pi(w)$ . We have

$$\int k^O u_c(c_0) d\pi = \int_{\underline{w}_N}^{\bar{w}_O} k^O u_c(c_0) d\pi \geq \bar{u}_c \int_{\underline{w}_N}^{\bar{w}_O} k^O d\pi, \quad (\text{OA16})$$

because (i)  $u_c(c_0) > \bar{u}_c$  for  $w < \underline{w}_N$ , and (ii) both  $k^O$  and  $u_c(c_0)$  are strictly decreasing in  $w$  for  $\underline{w}_N \leq w \leq \bar{w}_O$ , thus their covariance is positive, implying  $\int_{\underline{w}_N}^{\bar{w}_O} k^O u_c(c_0) d\pi \geq \bar{u}_c \int_{\underline{w}_N}^{\bar{w}_O} k^O d\pi$ .<sup>33</sup> Similarly, we have

$$\int k^N u_c(c_0) d\pi = \int_{\underline{w}_N} k^N u_c(c_0) d\pi \leq \bar{u}_c \int_{\underline{w}_N} k^N d\pi, \quad (\text{OA17})$$

because (i)  $u_c(c_0) < \bar{u}_c$  for  $w > \bar{w}_O$ , and (ii)  $k^N$  is strictly increasing in  $w$  for  $\underline{w}_N \leq w \leq \bar{w}_O$ , implying its covariance with  $u_c(c_0)$  is negative, and thus  $\int_{\underline{w}_N}^{\bar{w}_O} k^N u_c(c_0) d\pi \leq \bar{u}_c \int_{\underline{w}_N}^{\bar{w}_O} k^N d\pi$ . Furthermore, notice that at least one of the two inequalities (OA16) and (OA17) is strict, because the distribution of net worth  $\pi(w)$  is non-degenerate. Thus, combining (OA16), (OA17), and the market-clearing condition  $\int_{\underline{w}_N} k^N d\pi = \int_{\underline{w}_N}^{\bar{w}_O} k^O d\pi$ , we get (OA15). This proves Proposition 3.

We now discuss the case  $q = q^{FB}$ , which is not included in Proposition 3. We have  $\underline{w}_N = \bar{w}_O = \bar{w}$ . In this case, the individual choice of new and old capital for unconstrained firms is indeterminate. However, in the aggregate, market clearing implies  $\int_{\bar{w}} k^N d\pi(w) > \int_{\bar{w}} k^O d\pi(w)$ . Under a weak condition, our result on the sign of constrained inefficiency still obtains. Assume that  $k^N > k^O$  for all unconstrained firms.

Then,  $u_c(c_0)$  is strictly decreasing in  $w$ , we have

$$\int k^O u_c(c_0) d\pi - \int k^N u_c(c_0) d\pi > \int_{\bar{w}} k^O u_c(c_0) d\pi - u_c(c_0(\bar{w})) \int_{\bar{w}} (k^N - k^O) d\pi \quad (\text{OA18})$$

---

<sup>33</sup>See Schmidt (2003) for a proof of the sign of the covariance of monotone functions.

Using the market-clearing condition, we can rewrite (OA18) as follows

$$\int k^O u_c(c_0) d\pi - \int k^N u_c(c_0) d\pi > \int^{\bar{w}} k^O u_c(c_0) d\pi - u_c(c_0(\bar{w})) \int^{\bar{w}} k^O d\pi \quad (\text{OA19})$$

Because  $u_c(c_0) > u_c(c_0(\bar{w}))$  for  $w \leq \bar{w}$ , the right-hand side of (OA19) is positive, and thus also the left-hand side is positive. Hence, (OA15) holds.

### OA.3 Heterogeneity in Productivity

In this section, we analyze the model with productivity heterogeneity from Section 3.7 in more detail.

*Competitive Equilibrium with Financial Frictions.* A firm that draws initial net worth  $w$  and productivity  $s$  maximizes (6) subject to the budget constraints (7) and

$$sf(k_t^N + k_t^O) + q_{t+1}k_t^N = d_{1,t+1} + \beta^{-1}b_t, \quad (\text{OA20})$$

and the collateral constraint (9). Let  $v(w, s)$  denote the value function of the firm.

Denote the multipliers on the budget constraints by  $\mu_{0t}$  and  $\beta\mu_{1,t+1}$ , on the collateral constraint by  $\beta\lambda_t$ , and on non-negativity constraint for new and old capital by  $\underline{\nu}_t^N$  and  $\underline{\nu}_t^O$ , respectively. The optimality conditions are

$$1 + \phi_{d,t} = \beta [sf_k(k_t) + q_{t+1}] + \beta\theta\lambda_t q_{t+1} + \underline{\nu}_t^N \quad (\text{OA21})$$

$$q_t(1 + \phi_{d,t}) = \beta sf_k(k_t) + \underline{\nu}_t^O, \quad (\text{OA22})$$

and (12), where  $k_t = k_t^N + k_t^O$ .

A *stationary competitive equilibrium* is a set of policy functions mapping initial net worth and productivity to an allocation, that is, dividends, investment, and borrowing choices,  $\{d_0(w, s), d_1(w, s), k^N(w, s), k^O(w, s), b(w, s)\}$ , and a price of old capital  $q$ , such that firms maximize the present discounted value of dividends net of equity issuance cost,  $\forall (w, s) \in \mathcal{W} \times \mathcal{S}$ , and the market for old capital clears, that is,  $\int k^N(w, s) d\pi(w, s) = \int k^O(w, s) d\pi(w, s)$ .

In a stationary equilibrium, we can rewrite equations (OA21) and (OA22) as

$$\varphi_N(1 + \phi_d) = \beta [sf_k(k) + (1 - \theta)q] + \underline{\nu}^N \quad (\text{OA23})$$

$$q(1 + \phi_d) = \beta sf_k(k) + \underline{\nu}^O \quad (\text{OA24})$$

where  $\varphi_N = 1 - \beta\theta q$ . Following the same arguments we develop in Section 3.3, one can show

that  $q \geq q^{FB}$ . Moreover, for each value of  $s$ , there are thresholds  $\underline{w}_N(s) \leq \bar{w}_O(s) \leq \bar{w}(s)$  (with strict inequalities if  $q > q^{FB}$ ) such that: firms with  $w \leq \underline{w}_N(s)$  invest only in old capital; firms with  $w \in (\underline{w}_N(s), \bar{w}_O(s))$  invest  $\underline{k}(s)$  and invest in both new and old capital, and firms with  $w \geq \bar{w}_O(s)$  invest only in new capital; firms with  $w \geq \bar{w}(s)$  pay non-negative dividends and invest  $\bar{k}(s) \geq k^{FB}(s) \geq \underline{k}(s)$ .

We now show that the marginal equity issuance cost  $\phi_d(w, s)$  (or equivalently the marginal value of net worth  $v_w(w, s) = 1 + \phi_d(w, s)$ ) is weakly increasing in  $s$ , that is, higher productivity firms are more financially constrained, for a given level of net worth. First, consider firms that pay positive dividends. For these firms,  $\phi_d(w, s) = 0$ .

Now consider firms with  $\underline{\nu}^N > 0$  and  $\underline{\nu}^O = 0$ ; for such firms rewrite equation (OA23) as

$$1 + \phi_d(qk^O - w) = \beta \frac{sf_k(k^O)}{q}$$

where we use  $d_0 = w - qk^O$ ; totally differentiating with respect to  $s$ , we obtain  $\frac{dk^O}{ds} = \frac{\beta f_k(s)q^{-1}}{q\phi_{dd} - \beta s f_{kk}(k)q^{-1}} > 0$ . Thus,  $d_0$  is decreasing in  $s$ , which implies that  $\phi_d(w, s)$  (and  $v_w(w, s)$ ) is increasing in  $s$ .

Next, consider firms with  $\underline{\nu}^N = 0$  and  $\underline{\nu}^O = 0$ . In this case, combining equations (OA23) and (OA24), we can write  $1 + \phi_d = \beta R_O$ , where  $R_O = \frac{(1-\theta)q}{\wp^N - q}$ . Thus, all firms that are indifferent between new and old capital issue the same level of equity ( $\underline{d}_0$ ), and feature a constant marginal issuance cost  $\bar{\phi}_d$ , independent of productivity  $s$ . The total investment of such firms satisfies

$$\wp^N R_O = sf_k(\underline{k}(s)) + (1 - \theta)q,$$

which implies that  $\underline{k}(s)$  is increasing in  $s$ . Hence, also the indifference thresholds  $\underline{w}_N(s) = \underline{d}_0 + q\underline{k}(s)$  and  $\bar{w}_O(s) = \underline{d}_0 + \wp^N \underline{k}(s)$  are increasing in  $s$ .

Finally, for firms with  $\underline{\nu}^N = 0$  and  $\underline{\nu}^O > 0$ , rewrite equation (OA23) as

$$1 + \phi_d(\wp^N k^N - w) = \beta \frac{sf_k(k^N) + (1 - \theta)q}{\wp^N}.$$

Totally differentiating with respect to  $s$ , we obtain  $\frac{dk^N}{ds} = \frac{\beta f_k(s)\wp^N^{-1}}{\wp^N \phi_{dd} - \beta s f_{kk}(k)\wp^N^{-1}} > 0$ . Thus,  $d_0$  is decreasing in  $s$ , which implies that  $\phi_d(w, s)$  is increasing in  $s$ . We conclude that  $\phi_d(w, s)$  (and  $v_w(w, s)$ ) is weakly increasing in productivity  $s$  for all firms.

*Constrained Efficiency.* The planner maximizes

$$\int \left[ d_{10}(w, s) + \sum_{t=0}^{\infty} \beta^t (d_{0t}(w, s) - \phi(-d_{0t}(w, s)) + \beta d_{1,t+1}(w, s)) \right] d\pi(w, s), \quad (\text{OA25})$$

subject to the budget constraints (7) and (OA20), the collateral constraint (9), and the market-clearing condition for old capital. The first-order condition with respect to  $q_t$  is

$$\int k_t^O(w, s) (1 + \phi_{d,t}(w, s)) d\pi(w, s) = \int k_{t-1}^N(w, s) (1 + \theta \lambda_{t-1}(w, s)) d\pi(w, s),$$

which, in stationary equilibrium, can be rewritten as follows

$$\int k^O(w, s) \phi_d(w, s) d\pi(w, s) = \theta \int k^N(w, s) \phi_d(w, s) d\pi(w, s), \quad (\text{OA26})$$

where we used the market-clearing condition, as well as the fact that planner optimally sets the marginal equity issuance cost equal to the multiplier on the collateral constraint.

We now show that in stationary competitive equilibrium, the left-hand side of equation (OA26) is larger than the right-hand side, that is, the distributive externality dominates the collateral externality. We can bound the two sides of equation (OA26) as follows. First, notice that the marginal equity issuance cost  $\bar{\phi}_d$  is the lower bound for the marginal equity issuance cost of any firms with productivity  $s$  purchasing old capital, and the upper bound for the marginal equity issuance cost of any firms with productivity  $s$  purchasing new capital. Thus, for any productivity level  $s$ , we get

$$\int_w k^O(w, s) \phi_d(w, s) d\pi(w, s) \geq \bar{\phi}_d \int_w k^O(w, s) d\pi(w, s),$$

and

$$\int_w k^N(w, s) \phi_d(w, s) d\pi(w, s) \leq \bar{\phi}_d \int_w k^N(w, s) d\pi(w, s).$$

Next, recall that  $\bar{\phi}_d$  is independent of  $s$ . Hence, by summing both sides of these two inequalities over productivity levels, we obtain

$$\int k^O(w, s) \phi_d(w, s) d\pi(w, s) \geq \bar{\phi}_d \int k^O(w, s) d\pi(w, s),$$

and

$$\int k^N(w, s) \phi_d(w, s) d\pi(w, s) \leq \bar{\phi}_d \int k^N(w, s) d\pi(w, s).$$

The two bounds reported on the right-hand sides of these inequalities are equal to each other because of market clearing. Thus,  $\theta < 1$  implies

$$\int k^O(w, s) \phi_d(w, s) d\pi(w, s) > \theta \int k^N(w, s) \phi_d(w, s) d\pi(w, s),$$

which proves Proposition 4.

## OA.4 Relation to Models with Representative Entrepreneur and Assets in Fixed Supply

In this section, we connect our results on constrained efficiency in capital reallocation with a related class of models, that feature a representative infinitely-lived entrepreneur subject to collateral constraints, possibly impatient relative to the equilibrium interest rate, and with an asset in fixed supply, which we will refer to as land. This class of models includes the seminal work of Kiyotaki and Moore (1997) (henceforth KM) and the small-open-economy models with collateral constraints analyzed by Bianchi and Mendoza (2018) and Jeanne and Korinek (2019). While there is some variation in the specification of collateral constraints across these papers, we maintain our formulation of collateral constraints that depend on future asset prices, as in KM and Rampini and Viswanathan (2010, 2013).

First, we show that the representative-entrepreneur assumption in this class of models implies that there is no reallocation of land in stationary equilibrium. This lack of reallocation precludes any distributive effects of asset prices: As Dávila and Korinek (2018) show, distributive externalities depend on (i) heterogeneity in the marginal valuation of resources, and (ii) non-zero equilibrium trading.<sup>34</sup> We also connect this insight to the effects of unexpected changes in collateral values described by KM.

Second, we show that the fact that land is in fixed supply in these models, different from capital, which is endogenously produced in our model, does not affect the main insights on distributive externalities vs. collateral externalities in reallocation at the core of our paper. To illustrate this point, we recover a version of our main result on inefficiency in a model of land reallocation with overlapping generations of entrepreneurs – and hence reallocation in stationary equilibrium. Finally, we use this model to briefly discuss the role of impatience for the comparison of distributive and collateral externalities.

### OA.4.1 Representative Entrepreneur without Reallocation

We now describe an economy with a representative entrepreneur and a representative lender. The entrepreneur can be interpreted as the “farmer” in KM, or, alternatively, as the representative household residing in a small open economy. The lender can be interpreted as the “gatherer” in KM, or, alternatively, as a representative household in the rest of the world in small-open-economy models.

*Model.* A representative entrepreneur has preferences represented by the following util-

---

<sup>34</sup>This insight is also related to arguments developed in Stiglitz (1982) and Geanakoplos and Polemarchakis (1986), showing that incomplete-markets equilibria with no trading can be constrained efficient.

ity function

$$\sum_{t=0}^{\infty} \beta^t u(c_t), \quad (\text{OA27})$$

where  $\beta \leq R^{-1}$  is the discount factor,  $c_t$  is consumption,  $u_c > 0$ , and  $u_{cc} < 0$ . The entrepreneur has access to a technology  $y_t = f(k_{t-1})$  with  $f_k > 0$ ,  $f_{kk} < 0$ ,  $\lim_{k \rightarrow 0} f_k(k) = +\infty$ , where  $y_t$  is output and  $k_{t-1}$  is land.

A representative lender has preferences represented by the following utility function

$$\sum_{t=0}^{\infty} R^{-t} c_t^l, \quad (\text{OA28})$$

where  $R > 1$  is the inverse of the discount factor and  $c_t^l$  is consumption. The lender has access to a technology  $y_t^l = f^l(k_{t-1}^l)$  with  $f_k^l \geq 0$ ,  $f_{kk}^l \leq 0$ , where  $y_t^l$  is output and  $k_{t-1}^l$  is land. The case of a small open economy corresponds to lenders having an exogenous endowment, and not operating land, i.e.,  $f^l(k_{t-1}^l) = \bar{y}^l > 0$ .

The resource constraint of the economy is  $c_t + c_t^l = y_t + y_t^l$ . Land is in exogenous fixed supply,  $K = k_t + k_t^l$ . Entrepreneur and lender can trade land at price  $q_t$ , as well as a one-period bond  $b_t$ . Because of our assumptions on preferences, the gross interest rate is given by  $R$ . The budget constraints of entrepreneur and lender are as follows:

$$y_t + b_t = c_t + q_t(k_t - k_{t-1}) + Rb_{t-1} \quad (\text{OA29})$$

$$y_t^l + Rb_{t-1} = c_t^l + q_t(k_t^l - k_{t-1}^l) + b_t. \quad (\text{OA30})$$

Notice that our notation implicitly imposes equilibrium in the bond market, and we interpret a positive value of  $b_t$  as debt for the entrepreneur and assets for the lender.

The entrepreneur is also subject to the following collateral constraint

$$\theta q_{t+1} k_t \geq Rb_t, \quad (\text{OA31})$$

which limits borrowing by a fraction  $\theta < 1$  of the future resale value of the entrepreneur's land.

We define the Lagrangian of the entrepreneur's problem as follows

$$\begin{aligned} \mathcal{L} \equiv \sum_{t=0}^{\infty} \beta^t \{ & u(c_t) - \mu_t (c_t + q_t(k_t - k_{t-1}) + Rb_{t-1} - f(k_{t-1}) - b_t) \\ & + \beta \lambda_t (\theta q_{t+1} k_t - Rb_t) \}, \quad (\text{OA32}) \end{aligned}$$

where  $\beta^t \mu_t$  and  $\beta^{t+1} \lambda_t$  denote the multipliers on the budget constraint (OA29) and the collateral constraint (OA31), respectively.

The entrepreneur's optimality conditions with respect to land and debt are respectively

$$q_t u_c(c_t) = \beta u_c(c_{t+1}) (f_k(k_t) + q_{t+1}) + \beta \lambda_t \theta q_{t+1} \quad (\text{OA33})$$

$$u_c(c_t) = \beta R u_c(c_{t+1}) + \beta R \lambda_t. \quad (\text{OA34})$$

The lender maximizes utility (OA28) subject to the budget constraint (OA30) and a non-negativity constraint on land holdings, with multiplier  $\underline{\nu}_t^l$ . The lender's optimality condition with respect to land is

$$q_t = R^{-1} (f_k^l(k_t^l) + q_{t+1}) + \underline{\nu}_t^l. \quad (\text{OA35})$$

A *stationary competitive equilibrium* is defined as a time-invariant allocation  $\{c, c^l, k, k^l, b\}$  and a price of land  $q$  that satisfy the entrepreneur's and lender's optimality conditions, as well as the market-clearing condition  $K = k + k^l$ .

*Constrained Efficiency.* To analyze the constrained-efficiency properties of the stationary competitive equilibrium, we now consider the marginal effect of a change in the price of land on welfare. For simplicity, we consider a planner who assigns zero weight on the lender's utility; our insights are unchanged if we allow for a positive weight on the lender. The derivative of the entrepreneur's Lagrangian with respect to  $q_t$  is

$$\frac{\partial \mathcal{L}}{\partial q_t} = -\beta^t \mu_t (k_t - k_{t-1}) + \beta^t \lambda_{t-1} \theta k_t. \quad (\text{OA36})$$

In stationary equilibrium, the first term is equal to zero, because the amount of land owned by the entrepreneur is constant, whereas the second term is weakly positive, and strictly so if the collateral constraint is binding. In this case, the only pecuniary externality is the collateral externality, and an increase in the price of land would lead to an increase in welfare by relaxing the collateral constraint. An equivalent way to formulate this insight is to observe that even though cheaper land at date  $t$ , taking as given the price at  $t + 1$ , would seemingly benefit the entrepreneur by reducing the cost of investment at  $t$ , it would at the same time decrease the value of the entrepreneur's net worth by the same amount. Furthermore, it would make the collateral constraint tighter at date  $t - 1$ , resulting in an overall negative effect.

This result arises because there is no net trading of land in stationary equilibrium, so no equilibrium capital reallocation. Clearly, even if the planner assigned positive weight to the lender's utility, there would be no distributive externality, as the lender's amount of

land is also constant. This model may feature *misallocation* in stationary equilibrium, if, as in KM, the financial friction induces an allocation such that  $f_k(k) > f_k^l(k^l)$ . However, the model does not feature *reallocation*, in the sense that land is not traded in stationary equilibrium, resulting in no effect of the price of land on budget constraints, and thus no distributive externality.

*Relation to the KM mechanism.* To connect our efficiency analysis to the effects of asset-price changes in the KM model, we can rearrange equation (OA31) as follows, after substituting out debt  $b_t$  from the budget constraint (OA29):

$$(q_t - R^{-1}\theta q_{t+1})k_t - q_t k_{t-1} - f(k_{t-1}) + Rb_{t-1} + c_t \leq 0, \quad (\text{OA37})$$

or, equivalently,

$$k_t \leq \frac{1}{(q_t - R^{-1}\theta q_{t+1})} (w_t - c_t), \quad (\text{OA38})$$

where  $w_t \equiv q_t k_{t-1} + f(k_{t-1}) - Rb_{t-1}$  denotes the entrepreneur's net worth, which, importantly, also depends on the price of land.

Constraints (OA37) and (OA38) correspond to equations (4) and (7) in KM (pp. 219/220), which hold with equality in their model, determining the law of motion of the entrepreneur's land, whenever the collateral constraint is binding.<sup>35</sup> KM consider the following thought experiment: What would the effect of an *unexpected* increase in the *current and future* price of land on this constraint be? Notice that this marginal effect is different from the derivative (OA36), which accounts for the effects of current prices on past debt, and moreover treats the price at each date as a distinct variable. Nevertheless, to consider the KM thought experiment, we assume there are two consecutive dates such that  $q_t = q_{t+1} = q$  and differentiate both sides of inequality (OA37) with respect to  $q$ . We denote this derivative by  $\Delta^{KM}$ , and obtain

$$\Delta^{KM} = (1 - R^{-1}\theta)k_t - k_{t-1}. \quad (\text{OA39})$$

As KM argue, as long as the constraint is binding and  $f(k_{t-1}) - Rb_{t-1} - c_t < 0$ , that is, as long as there is sufficient leverage, we have  $\Delta^{KM} < 0$ , implying that an increase in the price of land would relax the collateral constraint, even after accounting for the effects of the price on the budget constraint. In stationary equilibrium, we have  $\Delta^{KM} = -R^{-1}\theta k < 0$ , because, as we argued, the effects of the price of land on the budget constraint other than through the collateral constraint cancel out, as the entrepreneur is keeping a constant amount of land.

We conclude that the collateral externality is the only pecuniary externality in the

---

<sup>35</sup>Under the technology assumption in KM, consumption  $c_t$  is a constant fraction of output, labeled as "perishable" output. Moreover, KM focus on the case in which  $\theta = 1$ .

stationary equilibrium of this model, and this insight about efficiency is closely related to the fact that an unexpected change in present and future collateral values, as analyzed by KM, relaxes the collateral constraint.

#### OA.4.2 Heterogeneous Entrepreneurs and Reallocation

We now consider a modification of this model and show how to recover our main insights on the importance of distributive externalities. Specifically, instead of assuming an infinitely-lived representative entrepreneur, we consider over-lapping generations of entrepreneurs, as in Section 3.6, which introduces heterogeneity among entrepreneurs and reallocation in equilibrium.

*Model.* For simplicity, we assume that entrepreneurs live for two dates and that all entrepreneurs are endowed with a common initial level of net worth  $w$ . We maintain all other assumptions from the model in the previous subsection, namely an infinitely-lived lender with linear preferences and a productive asset in fixed supply.

The representative entrepreneur born at date  $t$  has utility

$$u(c_{0t}) + \beta u(c_{1,t+1}) \tag{OA40}$$

with  $\beta \leq R^{-1}$ ,  $u_c > 0$ , and  $u_{cc} < 0$ . The budget constraints are

$$w + b_t = c_{0t} + k_t \tag{OA41}$$

$$f(k_t) + q_{t+1}k_t = c_{1,t+1} + Rb_{t-1}, \tag{OA42}$$

and the collateral constraint is given by equation (OA31) as before.

The optimality conditions with respect to land and debt are respectively

$$q_t u_c(c_{0t}) = \beta u_c(c_{1,t+1}) (f_k(k_t) + q_{t+1}) + \beta \lambda_t \theta q_{t+1} \tag{OA43}$$

$$u_c(c_{0t}) = \beta R u_c(c_{1,t+1}) + \beta R \lambda_t. \tag{OA44}$$

where, again,  $\beta \lambda_t$  denotes the multiplier on the collateral constraint. Notice that in this model there is always net trading of land, with young entrepreneurs being buyers and old entrepreneurs being sellers.

A *stationary competitive equilibrium* is defined as a time-invariant allocation  $\{c_0, c_1, c^l, k, k^l, b\}$  and a price of land  $q$  that satisfy the entrepreneurs' and lender's optimality conditions, as well as the market-clearing condition  $K = k + k^l$ .

*Constrained Efficiency.* As in Section 3.6 and Appendix OA.2, we consider a planner who maximizes the present discounted value of utilities of all generations of entrepreneurs,

with discount factor  $\beta$

$$u(c_{10}) + \sum_{t=0}^{\infty} \beta^t (u(c_{0t}) + \beta u(c_{1,t+1})),$$

subject to all budget constraints, collateral constraints, and market-clearing conditions.

The marginal effect of the price of land  $q_t$  on aggregate welfare is given by

$$-\beta^t (u_c(c_{0t}) - u_c(c_{1t})) k_t + \beta^t \lambda_{t-1} \theta k_t. \quad (\text{OA45})$$

The two marginal-utility terms represent the distributive externality, due to the fact that young entrepreneurs buy land, whereas old entrepreneurs sell land in equilibrium. Thus, as long as they have different marginal utility from consumption, the aggregate distributive effect of a price change is non-zero. The last term involving the multiplier  $\lambda_{t-1}$  denotes the collateral externality, because the price of land affects the collateral constraint in the previous period.

Using equation (OA44) to substitute out  $\lambda_{t-1}$ , this expression can be rewritten as

$$-\beta^t [(u_c(c_{0t}) - u_c(c_{1t})) - \beta^{-1} R^{-1} \theta (u_c(c_{0,t-1}) - \beta R u_c(c_{1t}))] k_t. \quad (\text{OA46})$$

*Case  $\beta = R^{-1}$ .* We now show that under the baseline assumption on discounting in our paper, which is  $\beta = R^{-1}$ , this derivative is negative in stationary equilibrium, because buyers of land have a higher marginal utility than sellers, and moreover the distributive externality dominates the collateral externality. To see this, observe that  $\beta = R^{-1}$  and equation (OA44) imply  $u_c(c_0) - u_c(c_1) \geq 0$ . Furthermore, the expression in (OA46) becomes

$$-\beta^t (u_c(c_0) - u_c(c_1)) (1 - \theta) k \leq 0, \quad (\text{OA47})$$

with strict inequality if the collateral constraint binds. Thus, when  $\beta = R^{-1}$ , introducing heterogeneity and equilibrium reallocation in the model with assets in fixed supply overturns the result on the sign of inefficiency obtained in representative-entrepreneur models. The distributive externality dominates the collateral externality, consistent with the main insight in our model with endogenous investment.

*Case  $\beta < R^{-1}$ .* We now discuss the role of impatience for pecuniary externalities in the reallocation of land. In the case of relatively impatient entrepreneurs, i.e.,  $\beta < R^{-1}$ , we cannot sign the aggregate welfare effect of the price of land unambiguously in general. First, notice that under sufficient impatience, equation (OA44) is consistent with young entrepreneurs having a *lower* marginal utility than old entrepreneurs. Second, notice that,

as equation (OA46) highlights, the distributive externality from the price  $q_t$  generates an aggregate welfare effect at date  $t$ , whereas the collateral externality relaxes a constraint at date  $t - 1$ . When  $\beta = R^{-1}$ , this timing difference is exactly offset by the discounting of the value of collateral in the collateral constraint. In contrast, when  $\beta < R^{-1}$ , the difference in timing between the two externalities implies that the collateral externality is relatively more important, other things equal, as reflected by the factor  $\beta^{-1}R^{-1} > 1$  that multiplies the corresponding terms in equation (OA46).

## OA.5 Additional Optimality Conditions for Quantitative Model

In this section, we provide the optimality conditions for the planner's problem, restricted not to distort investment in old capital, discussed at the end of Section 4.4. We denote by  $\psi_t(s^a)$  the multipliers on the old-capital Euler equations, which are now constraints for the planner:

$$q_t(1 + \phi_{d,t}(s^a)) = \beta \mathbb{E}_t [s_{a+1} f_k(k_t(s^a)) g_{O,t}(s^a) + (1 - \delta^O) q_{t+1}] (1 + (1 - \rho) \phi_{d,t+1}(s^{a+1})) \\ + \beta \theta \lambda_t(s^a) (1 - \delta^O) q_{t+1}.$$

In formulating this constraint on the planning problem, we need to substitute a differentiable expression for the Lagrange multiplier on the collateral constraint  $\lambda_t(s^a)$ . We follow, for instance, Jeanne and Korinek (2019) and use the competitive-equilibrium optimality condition for debt to substitute

$$\lambda_t(s^a) = \phi_{d,t}(s^a) - (1 - \rho) \mathbb{E}_t \phi_{d,t+1}(s^{a+1}). \quad (\text{OA48})$$

The planner's optimality condition for new capital is

$$1 + \phi_{d,t}(s^a) = \beta \mathbb{E}_t [s_{a+1} f_k(k_t(s^a)) g_{N,t}(s^a) + (1 - \delta^N (1 - q_{t+1}))] (1 + (1 - \rho) \phi_{d,t+1}(s^{a+1})) \\ + \beta \theta \lambda_t(s^a) (1 - \delta^N (1 - q_{t+1})) + \beta \delta^N \eta_{t+1} + \psi_t(s^a) \frac{\partial O_t(s^a)}{\partial k_t^N(s^a)}$$

with

$$\frac{\partial O_t(s^a)}{\partial k_t^N(s^a)} = -\beta \mathbb{E}_t s_{a+1} (f_{kk}(k_t(s^a)) g_{N,t}(s^a) g_{O,t}(s^a) + f_k(k_t(s^a)) g_{NO,t}(s^a)) (1 + (1 - \rho) \phi_{d,t+1}(s^{a+1})) \\ + \phi_{dd,t}(s^a) (q_t - \beta \theta (1 - \delta^O) q_{t+1}) + \beta (1 - \rho) \mathbb{E}_t \phi_{dd,t+1}(s^{a+1}) [s_{a+1} f_k(k_t(s^a)) g_{N,t}(s^a) + (1 - \delta^N (1 - q_{t+1}))] \\ \times [s_{a+1} f_k(k_t(s^a)) g_{O,t}(s^a) + (1 - \delta^O) (1 - \theta) q_{t+1}].$$

The optimality condition for old capital is

$$q_t(1 + \phi_{d,t}(s^a)) = \beta \mathbb{E}_t [s_{a+1} f_k(k_t(s^a)) g_{O,t}(s^a) + (1 - \delta^O) q_{t+1}] (1 + (1 - \rho) \phi_{d,t+1}(s^{a+1})) \\ + \beta \theta (1 - \delta^O) \lambda_t(s^a) q_{t+1} - \eta_t + \beta (1 - \delta^O) \eta_{t+1} + \psi_t(s^a) \frac{\partial O_t(s^a)}{\partial k_t^O(s^a)}$$

with

$$\frac{\partial O_t(s^a)}{\partial k_t^O(s^a)} = -\beta \mathbb{E}_t s_{a+1} (f_{kk}(k_t(s^a)) (g_{O,t}(s^a))^2 + f_k(k_t(s^a)) g_{OO,t}(s^a)) (1 + (1 - \rho) \phi_{d,t+1}(s^{a+1})) \\ + \phi_{dd,t}(s^a) q_t (q_t - \beta \theta (1 - \delta^O) q_{t+1}) \\ + \beta (1 - \rho) \mathbb{E}_t \phi_{dd,t+1}(s^{a+1}) [s_{a+1} f_k(k_t(s^a)) g_{O,t}(s^a) + (1 - \delta^O) q_{t+1}] \\ \times [s_{a+1} f_k(k_t(s^a)) g_{O,t}(s^a) + (1 - \delta^O) (1 - \theta) q_{t+1}].$$

The optimality condition for debt is

$$\phi_{d,t}(s^a) = (1 - \rho) \mathbb{E}_t \phi_{d,t+1}(s^{a+1}) + \lambda_t(s^a) - \psi_t(s^a) \frac{\partial O_t(s^a)}{\partial b_t(s^a)}$$

with

$$\frac{\partial O_t(s^a)}{\partial b_t(s^a)} = -\phi_{dd,t}(s^a) (q_t - \beta \theta (1 - \delta^O) q_{t+1}) \\ - (1 - \rho) \mathbb{E}_t \phi_{dd,t+1}(s^{a+1}) [s_{a+1} f_k(k_t(s^a)) g_{O,t}(s^a) + (1 - \delta^O) (1 - \theta) q_{t+1}].$$

Notice that this condition implies a difference between the value of this multiplier as perceived by firms (in a competitive equilibrium with taxes, that is, equation (OA48)) and as perceived by the planner. We verify numerically that this deviation is quantitatively unimportant, and we also solve an alternative problem in which the planner does not internalize the effect of debt choices on the Euler equation for old capital (the term  $\frac{\partial O_t(s^a)}{\partial b_t(s^a)}$ ), thus aligning the values of this multiplier for firms and planner, finding similar results.

The constrained-efficient price of old capital satisfies

$$\begin{aligned} \sum_{a=0}^{\infty} \gamma_a \sum_{s^a} p(s^a) k_t^O(s^a) (1 + \phi_{d,t}(s^a)) = \\ \sum_{a=0}^{\infty} \gamma_a \sum_{s^{a+1}} p(s^{a+1}) [\delta^N k_{t-1}^N(s^a) + (1 - \delta^O) k_{t-1}^O(s^a)] (1 + (1 - \rho) \phi_{d,t}(s^{a+1}) + \theta \lambda_{t-1}(s^a)) \\ + \sum_{a=0}^{\infty} \gamma_a \sum_{s^a} p(s^a) (\psi_t(s^a) \frac{\partial O_t(s^a)}{\partial q_t} + \psi_{t-1}(s^a) \beta^{-1} \frac{\partial O_{t-1}(s^a)}{\partial q_t}) + \zeta_t \end{aligned}$$

with

$$\frac{\partial O_t(s^a)}{\partial q_t} = 1 + \phi_{d,t}(s^a) + \phi_{dd,t}(s^a) q_t (k_t^O(s^a) - \delta^N k_{t-1}^N(s^{a-1}) - (1 - \delta^O) k_{t-1}^O(s^{a-1}))$$

and

$$\begin{aligned} \frac{\partial O_{t-1}(s^a)}{\partial q_t} = -\beta(1 - \delta^O)(1 + \theta \phi_{d,t-1}(s^a) + (1 - \theta)(1 - \rho) \mathbb{E}_{t-1} \phi_{d,t}(s^{a+1})) \\ + \beta(1 - \rho) \mathbb{E}_{t-1} \phi_{dd,t}(s^{a+1}) (\delta^N k_{t-1}^N(s^a) + (1 - \delta^O) k_{t-1}^O(s^a) - k_t^O(s^{a+1})) \\ \times [s_{a+1} f_k(k_{t-1}(s^a)) g_{O,t-1}(s^a) + (1 - \delta^O)(1 - \theta) q_t]. \end{aligned}$$

The price of old capital affects the planner's value through its effects on the old-capital Euler equations, which the planner takes as constraints. These additional effects are summarized by the terms  $\frac{\partial O_t(s^a)}{\partial q_t}$  and  $\frac{\partial O_{t-1}(s^a)}{\partial q_t}$ .

## OA.6 Solution Method for Quantitative Model

In this section, we discuss the solution method for the quantitative model. We compute the stationary constrained-efficient allocation, in the case in which the planner chooses both new and old capital, using the following iterative procedure:

1. Guess a value for the multiplier on the market clearing condition for old capital  $\eta$ .
  - (a) Guess a value for the price of old capital  $q$ .
  - (b) Solve for the firm policy functions on a grid for net worth  $w$  and productivity  $s$ , using the optimality conditions (49), (50), and (47) evaluated in stationary equilibrium.
  - (c) Obtain the stationary distribution of net worth and productivity by simulating a continuum of firms.

(d) Check the market-clearing condition (35) and update the guess for the price  $q$  accordingly, until convergence.

2. Evaluate the optimality condition for the price of old capital (51) and update the guess for  $\eta$  accordingly, until convergence.

The stationary competitive equilibrium is a special case of steps (a)-(d) with  $\eta = 0$ .

## OA.7 Additional Quantitative Results and Sensitivity

This section provides additional figures related to the quantitative analysis of Sections 5 and 6. Figure OA2 displays the optimal tax rates on new and old capital that implement the constrained-efficient allocation in our calibrated model. Figure OA3 plots the transition

Figure OA2: Optimal tax rates. Left panel: tax rate on new capital (a negative value denotes a subsidy); right panel: tax rate on old capital. The  $x$ -axes report net worth  $w$ . Thick red lines refer to the high productivity realization; thin blue lines refer to the low realization.

dynamics associated with the implementation of the optimal tax rate on new capital (at  $t = 0$ ), common for all firms and constant over time, starting from the competitive equilibrium without policy intervention (at  $t = -1$ ).

Figure OA3: Equilibrium transition dynamics associated with the optimal constant tax rate  $\tau^N$ , common for all firms. Top panel: tax rate  $\tau^N$ ; middle panel: price of old capital  $q_t$ ; bottom panel: aggregate stock of old capital  $K_t^O$ .
